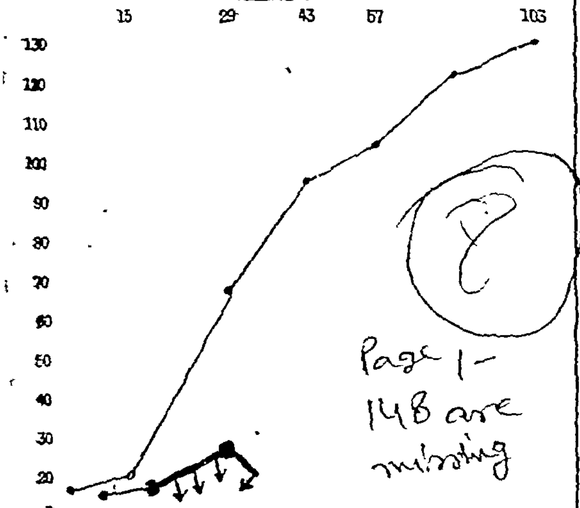
[illegible] or two days longer on that diet. After the change of [illegible] there was a rapid and immediate improvement in the condition of all three animals. The result was even more striking than in the case of the three animals the diet of which had been changed to bread and sweet milk (see chart). All three animals were alive and in fair condition in the middle of October, their average weight at that time (128 grammes) being, however, below the normal.

B. In the second generation.—The recuperative power in the second generation of meat-fed rats was tested in four animals taken from two litters, other four animals from the same litters being employed as controls. After weaning, the eight were kept on a horse-flesh diet for two weeks; in this period their weight was little more than maintained (see Chart 8). Two from each litter were then transferred to a bread and skim-milk dietary, the remaining four being kept on the horse-flesh diet. All four meat-fed subjects succumbed in two to three weeks, the four transferred rats living and gaining in weight in the striking manner shown on the chart. The later history of these four rats is of great interest. The animals were killed when eight months old, their average weight being 150 grammes. Their health during the later months was very defective, the symptoms manifested being, in order of onset and severity (*a*) accelerated and noisy respirations, dry râles being audible a considerable distance from the hutch and (*b*) a dry condition of the skin with roughness and loss of hair. These clinical features considered alongside of the other facts recorded in this paper point to the general conclusion that the symptoms from which the animals suffered in later life were etiologically related to the use of the defective dietary in very early life. There can, it appears to me, be no reasonable doubt that the symptoms observed were the result of the premature loss of some vital function or functions, and more especially of those concerned in warding off bacterial infection from the respiratory, and probably also the alimentary, tract.

CHART 8.



Recuperative power in second generation of meat-fed rats. The faint line equals the average weight of four rats bred on an ox-flesh diet which were transferred to a bread and skim milk diet at the age of six weeks. The dark line equals the average weight of four rats from the same litters which were not transferred but were kept on the meat diet.

Summary of results.—These experiments prove that the excessive use of a meat diet in rats is attended with the following results: (1) growth is retarded; (2) sterility is induced if the diet is commenced in very early life; (3) the power of lactation is diminished; (4) a permanent weakening of the resisting power of the animals is induced by the use of an excessive meat diet in early life, the animals succumbing to disease at an unusually early age; and (5) there is a high death-rate in the offspring of animals fed on an excessive meat diet.

Commentary.—The facts recorded have an interesting bearing on the two questions of physical deterioration and high infantile mortality that are engaging medical attention at the present time. With regard to these conditions there is no doubt that not one but several factors are concerned in their production. There is equally little doubt that among these factors the question of diet occupies a foremost place. The defects in a diet may lie in one of several directions. The food may be of fair nutritive value but insufficient in amount; on the other hand, it may be of high nutritive value, excessive in amount, and of a nature which exercises an injurious effect on the organs and tissues. It is important that some light on this subject should be looked for from experimental medicine, and in view of the increasing prevalence of the consumption of animal food in this country it is of special importance to determine the effects on the organism of an excess of animal proteid food. The main interest of my experimental results lies in the clear evidence submitted that an excessive meat diet can itself induce in animals—whose dietetic habits are fairly akin to those of man—some of the most prominent symptoms of physical deterioration—viz., defective general physique, deficient power of lactation, diminished fertility, and a high infantile mortality. I believe that these symptoms are, to an important extent, comparable to those prevailing in the human subject at the present time, the symptoms in man having, however, been established in a more gradual manner, their onset being contributed to by the operation of other etiological factors.

Some points of practical importance are brought out in the record. Of these the most noteworthy is the importance of a proper dietary in very early life. My experiments showed that the use of an excessive meat *régime* in early life induced a serious and permanent weakness of the animals, which, however, remained for a long time latent after the substitution of a physiological dietary. Clinical experience has led me to think that we have here also a close parallel in diseases in the human subject, and more especially in the class of affections commonly included under the terms gout and goutiness. Be that as it may, the experimental results indicate the importance of directing particular attention to the early dietetic history of patients so far as these are obtainable. The necessity for this will be further emphasised by the subsequent records of the structural changes in the organs and tissues observed in the course of these experiments.

The experiments referred to in this paper were conducted in the physiological laboratory of the University of Edinburgh with the assistance of grants from the Moray fund of the University and the Carnegie trust, and I take this opportunity of expressing my great indebtedness to Professor Schäfer for invaluable assistance received throughout the investigation.

Edinburgh.

OUTBREAK OF PNEUMONIA IN A REFORMATORY SCHOOL.

By THOMAS OLIVER, M.A. DURH., M.D., LL.D. GLASG., F.R.C.P. LOND.,
PHYSICIAN TO THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-UPON-TYNE.

THE following notes are published in the hope that other physicians drawing their experience from a larger field may be induced to express their views upon some such similar outbreak with which they may have perchance been brought into contact. The outbreak to which I refer occurred fully four years ago. Although at the time I was much interested in the illness I have refrained from publishing the notes of the cases in the hope that some new circumstance might arise which would throw fresh light upon an epidemic of pneumonia that was as sudden in its onset as it was obscure in its causation. I have been informed that outbreaks of pneumonia have recently occurred in other reformatory schools in England and in Scotland, the origin and causation of which are equally mysterious.

Admittedly a microbial disease, pneumonia or pneumonic fever is not a pathological entity due to one and the same micro-organism. The malady owns many causes and yet while an attempt might be made to include under the term pneumonia only the croupous form of the disease, the result of a specific pneumococcus, and to regard all other forms as simply inflammation of the lungs, this would not advance our knowledge, for while the pneumococcus is without doubt the cause of pneumonia there are cases of pneumonia in which this organism is not detected. Asthenic types of the disease are associated with a variety of micro-organisms. Croupous pneumonia, or that due to the pneumococcus of Fränkel, is usually preceded by a rigor, is attended by physical signs pointing to consolidation of lung, runs a definite course, and reaches a crisis within nine days, but it is seldom a disease that becomes epidemic. When it assumes this character it is more than likely that the malady is not due to the pneumococcus alone but to other micro-organisms as well, and therefore the result of a mixed infection.

The industrial school to which I was called by the visiting medical officer is in the neighbourhood of Newcastle-upon-Tyne. It has accommodation for 200 boys and is nearly always full. During the month of April of the particular year in question the only entries in the log-book were one case of Pott's fracture, one case of skin disease, and three cases of abscess. On May 17th two boys, aged 13 years respectively, were seized with pneumonia; five days later (May 22nd) other three boys, also aged about 13 years, were added to the list; ten days later (June 1st) a sixth case occurred in a boy 14 years of age; on June 5th two more cases in boys aged nine and 12 years respectively and on June 23rd the ninth case occurred. This boy, aged 15 years, had complained of headache in the afternoon but so slight did his ailment seem that it was not considered necessary by the governor to summon the medical officer. During the night the nurse, who was attending to some boys in the dormitory, gave him at his own request a drink of milk. A few hours later the lad was found dead in bed. On the following day I made a necropsy. The body was that of a well-nourished boy. Rigor mortis was passing off. There were no signs of external bruising. The pericardium contained a small quantity of free fluid. On the surface of the heart were numerous small petechial hæmorrhages. The heart itself was healthy. There was a small quantity of serous fluid in the left pleural cavity. The base of the left lung was adherent to the diaphragm. On section the lower lobe of the left lung was found to be the seat of the early stage of pneumonia. Beyond being slightly adherent to the diaphragm the right lung presented nothing abnormal. The stomach contained about two ounces of grumous fluid; its mucous membrane as well as that of the intestine was healthy. The liver was large but healthy. The spleen was very much enlarged and pulpy. The kidneys were congested There were no enlarged glands in the mesentery and no signs of tubercle or of peritonitis. Beyond being paler on its surface than usual the brain presented nothing abnormal The blood was extremely fluid. The opinion come to by the medical officer and myself was that the boy had died in collapse in the early stage of pneumonia. A bacteriological examination of the blood and fluids was unfortunately not made.

Looking back upon the history of the outbreak it will be observed that in all eight cases of pneumonia occurred between May 18th and June 5th—i.e., in 18 days—and that the ninth, the last and only fatal case occurred 15 days later. In the expectoration of one of the first two boys who fell ill tubercle bacilli were found in the fourth week, yet this lad not only made a good recovery, but three years after the illness is reported to be quite well and strong and earning his living as a labourer at some iron works. In none of the other cases were tubercle bacilli found. The after histories of these lads obtained four years subsequently are interesting. The youths are all quite well.

In their clinical aspects the illnesses were ordinary croupous pneumonia. There was nothing unusual or peculiar in the course they ran. In trying to determine the cause of the outbreak we were struck by the fact that most of the cases occurred in one large dormitory in which the sleeping accommodation was overcrowded and the ventilation of the room was defective. The window lighting of this ward, too, was deficient. A new range of windows was put in the blank wall. The other points were at once attended to. Since then not only have there been no fresh cases of pneumonia but the health of the boys has been remarkably good.

I am but giving expression to the opinion of my confrères when I say that it is no uncommon thing when pneumonia is prevalent in a town for the disease to break out and linger in certain streets compared with others. A [illegible] while ago I was asked to see in consultation in a neighbouring town several cases of pneumonia in succession within the space of three weeks. Most of the cases occurred in the street in houses not far distant from each other, also in two or three adjacent streets. Similar outbreaks in institutions, such as schools, barracks, &c., and of these have been traced to the escape of sewer air the sleeping rooms. When several cases of pneumonia thus occurred in close succession there has generally been overcrowding as well.

The fact that death occurred in the case above mentioned within 24 hours of the commencement of the illness rather removes the case from the category of ordinary pneumonia, for in croupous pneumonia it is rare for death to occur before the third or fourth day. Much depends in any case upon the virulence of the microbe and the resistance of the individual. Irritant gases when respired provoke acute bronchial and pulmonary congestion but non-irritant gases are not considered to have any such effect and yet I have found animals die from acute congestion of the lungs after the inhalation of carbon monoxide, which is not usually regarded as an irritant; and men are known to have died from a similar cause, the only gross lesion found after death being acute inflammation of the lungs. What there is in sewer air over and above the gas itself or combination of gases to cause pneumonia we need not discuss. It is for our present purpose enough to know that sewer air can cause pneumonia. Typhoid fever and intestinal toxins from improper food, as in the Middlesbrough epidemic of 1889, are also causes of pneumonia and so too is influenza. There was nothing in the outbreak at the reformatory school to suggest an influenzal origin. The rapidity of development, the crowding of the cases into a brief period of time and the fact that most of them occurred in one dormitory, all point to the cause or causes having been in the dormitory itself, an opinion confirmed by the disappearance of the malady after the ventilation had been improved and certain structural alterations and rearrangement of the sleeping accommodation had been effected. The condition of the lung found in the boy, accompanied by petechial hæmorrhages on the surface of the heart, recalls some other form of toxæmia than that caused by the pneumococcus, but since under the term pneumonia are included as already stated, many diseases, not all of them due to one and the same microbe, it is impossible in the present state of our knowledge to do other than include the above under the wide category of pneumonia.

Newcastle-upon-Tyne.

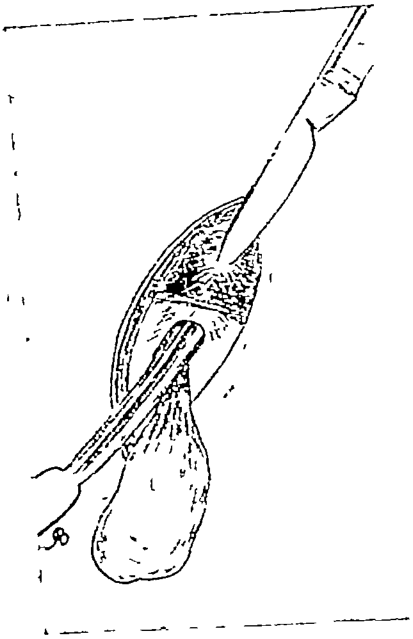
THE RADICAL CURE OF FEMORAL HERNIA.

By ASLETT BALDWIN, F.R.C.S. Eng.,
SENIOR ASSISTANT SURGEON TO THE WEST LONDON HOSPITAL; LECTURER
ON PRACTICAL SURGERY AND TEACHER OF OPERATIVE SURGERY
AT THE WEST LONDON POST-GRADUATE COLLEGE, WEST
LONDON HOSPITAL, HAMMERSMITH-ROAD, W.

For some years past I have been practising the following operation for the cure of femoral hernia with, as far as can be ascertained, a uniformly successful result. One of the patients, a woman three months pregnant, had an irreducible rupture; she went to full term. The child is now three and a half years old and there has been no sign of a recurrence of the hernia. I have performed the operation upwards of 20 times; all the cases healed by first intention and caused no trouble whatever.

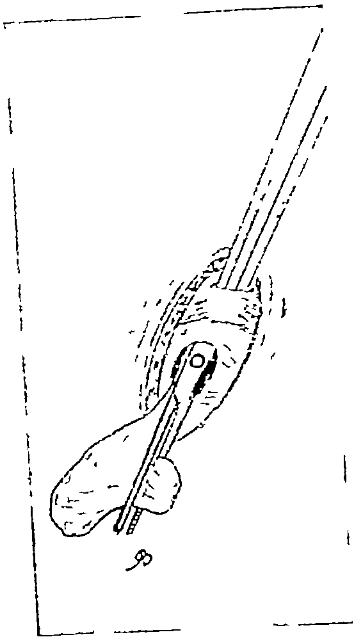
Method of operation.—A curved incision about one and a half or two inches long is made over the saphenous opening. The sac is isolated and more or less cleared of fat. If not already back the hernia is reduced. A slightly curved hernia director is now introduced up the crural canal in front of the sac and when its point is behind Poupart's ligament it is moved laterally so as for a short distance to strip off the peritoneum from the posterior surface of the transversalis fascia. The point of the director is now pushed farther upwards and tilted forwards so as to make the aponeurosis of the external oblique muscle project about half an inch above Poupart's ligament. A small transverse incision is now made through the aponeurosis, parallel to its fibres, on to the point of the director (Fig. 1), which is now pushed up through the opening. The latter is only just large enough to allow of this being done. A sinus forceps, Spencer Wells forceps, or small nasal polypus forceps—the last, being slightly curved, is more convenient—is now introduced through the opening.

FIG 1.



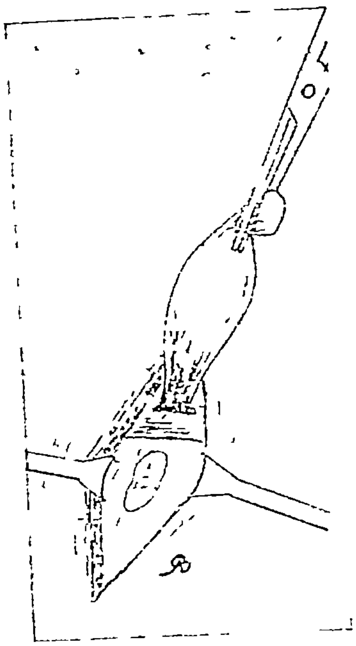
An incision being made on to the point of a director which has been passed up the crural canal and its point tilted forwards about half an inch above Poupart's ligament.

FIG. 2



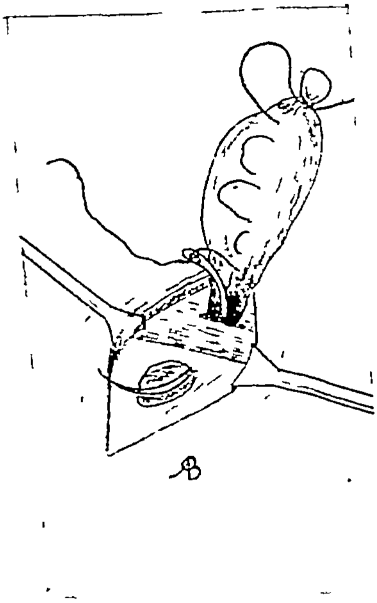
Sinus forceps passed through the opening above Poupart's ligament, behind the ligament and through the saphenous opening, and made to grasp the fundus of the sac.

FIG. 3.



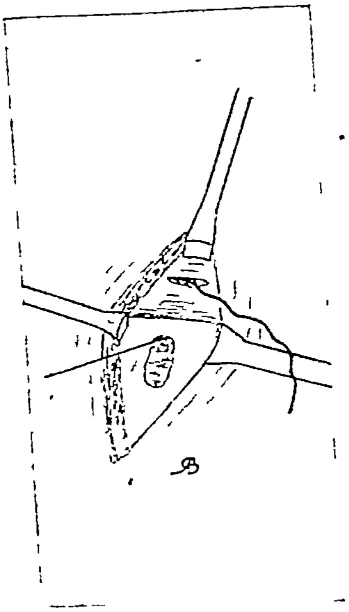
The sac pulled out through the opening above Poupart's ligament.

FIG 4.



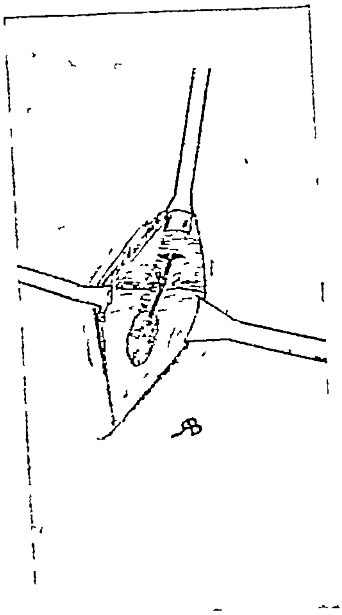
Needle threaded as described passed through the neck of the sac through the opening above Poupart's ligament, across the transverse ramus of the pubes, through the pectineus muscle and out through the saphenous opening.

FIG. 5.



The sac has been passed back through the opening above Poupart's ligament and rests behind the latter and the transversalis fascia.

FIG. 6.



The two ends of the thread are tied, fixing the sac in its place and obliterating the crural canal.

passed behind Poupart's ligament, and made to project from the saphenous opening; as this is done the director is withdrawn; in its descent it guides the forceps and prevents it from catching. The fundus of the sac is now seized by the forceps (Fig. 2), which is completely withdrawn, dragging the sac out through the opening in the external oblique aponeurosis (Fig. 3). The sac is now pulled out as much as possible and ligatured at the top of its neck. By this manœuvre no pouch is left in which recurrence may take place. A suture (silk, silkworm gut, and chromicised catgut have been used) is now passed through the fundus of the sac, the suture is drawn through to its middle and then tied, thus leaving two free ends of equal length, or this may be done before the sac is pulled up through the opening in Poupart's ligament, the thread being seized by the forceps and used to pull up the sac. But if the sac is large the thread may tear out and time be lost. One end is now threaded in a strong curved needle, one which will not rotate in the forceps which grasps it. The needle is now passed backwards and forwards through the sac several times, starting at the fundus and finishing at the neck, as described by Macewen for puckering the sac. The needle is now grasped in forceps, or a needle on a handle may be used, and its point is passed through the hole above Poupart's ligament, through the neck of the sac, down to the transverse ramus of the pubes, then by a turn of the wrist the point is made to slide forwards across the pubic bone, as close to it as possible, then to pierce the pectineus muscle and to appear through the inner part of the saphenous opening (Fig. 4). The needle is pulled through, bringing its thread with it. By drawing on the thread and by tucking the sac back again through the hole above Poupart's ligament by means of a stout probe or similar blunt instrument the sac disappears from view and comes to rest in a puckered-up condition behind the transversalis fascia and at the top of the crural canal, which it effectually roofs in. By this time the other end of the thread is hanging out of the hole above Poupart's ligament (Fig. 5). It is tied fairly firmly, but not too tightly, to the thread which projects from the saphenous opening; this fixes the sac in its place and fixes Poupart's ligament to the pectineus muscle, so obliterating the crural canal (Fig. 6). If necessary a second suture may be put in for this purpose but nearer the pubic spine. A suture is now put in to close the hole above Poupart's ligament and the skin incision is closed. Thus there are three distinct checks against the recurrence of the hernia: (1) the sac is ligatured higher up than is possible by the ordinary method and leaves no peritoneal pouch; (2) the sac is used as a buffer or roof above the crural canal; and (3) Poupart's ligament is approximated to the pectineus muscle and obliterates the crural canal.

It may be urged that the sac will slough and cause trouble. This does not take place. It no doubt becomes vascularised, converted into granulation tissue, and ultimately into fibrous tissue. Of course asepsis is necessary.

In strangulated hernia, where it has appeared safe to leave the sac and where time was precious, I have modified the operation by pushing the sac up through the canal, after having made a little space for it as before, and then sutured Poupart's ligament to the pectineus muscle. The result was perfectly satisfactory; but this method is not such a guarantee against relapse as the former, which I believe to be a genuine radical cure. The operation does not take long and no new or special instruments are required.

Manchester-square, W.

CESSATION OF THE PULSE DURING THE ONSET OF EPILEPTIC FITS,

WITH REMARKS ON THE MECHANISM OF FITS.

By A. E. RUSSELL, M.D. LOND., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE WEST LONDON HOSPITAL.

THE following case seems worthy of record, inasmuch as it is in accord with other cases which led many years ago to the enunciation of an explanation of the mechanism of epileptic fits which has, however, of late years fallen into discredit.

The patient was a man, aged 21 years. He had suffered from epileptic fits all his life. A maternal aunt had also been subject to fits all her life. The patient's fits commenced with an aura which was referred to by him as an indescribable sensation in his navel. As he experienced a well-marked aura he was given some capsules of amyl nitrite with instructions to break one and inhale it when he perceived the aura. This he was in time to do on one occasion and affirmed most positively that it warded off the fit. The majority of his fits occurred in bed at night; sometimes in his waking moments. Any emotional excitement was very apt to precipitate a fit. On April 21st he developed a fit in the out-patient room. He uttered a cry and was seen to be rubbing his hands together. His pulse was immediately examined for but was not palpable. He was just commencing the stage of tonic spasm when the wrist was seized. This tonic spasm lasted for about three-quarters of a minute, perhaps a minute. Dr. E. W. Hedley, who examined the other wrist also corroborates the absence of the pulse during the tonic phase. It was not easy to determine exactly when the pulse returned but we feel certain that the pulse did not return until the clonic phase. At first it was feeble but as the fit subsided it became fuller and stronger.

Dr. W. T. Harris of Chiswick has kindly told me of another case which occurred in his practice. A man came to have a tooth extracted. While applying the forceps the patient's head suddenly fell back and his face turned exceedingly pale. On feeling for his pulse Dr. Harris found it to be absent. Thinking that it was a severe syncopal attack he attempted to give the patient some sal-volatile but clonic convulsions intervened. These were slight and very transient, consciousness being regained almost immediately. Within a few minutes, however, the patient again turned very pale and became unconscious with tonic spasm. Dr. Harris again noted complete absence of the radial pulse, but at the commencement of the clonic stage a feeble pulse appeared at the wrist which gradually improved as the fit subsided. On questioning the patient he acknowledged having had two previous epileptic fits.

Remarks.—Cessation of the pulse preceding the onset of an epileptic fit has been noticed before. Thus Moxon[1] when examining a patient with cardiac dropsy notes: "I was feeling his pulse carefully; the beats were regular and of moderate strength.......I missed one, then another beat, and then found the pulse to have stopped so entirely that it made me look up suddenly at the man to see what was the matter. His face had become very pale, his head was turned towards his left shoulder, and the lip and cheek were twitching; the spasms then affected his arms, and he passed into a severe epileptic convulsion. At the time when I first noticed the pulse to disappear the man's arm was quite still. I tried to feel the pulse during the convulsion but there was so much muscular movement that I could not distingush it." On another occasion Moxon was examining the pulse of a man who had been admitted to hospital for uræmic vomiting and convulsions. "I took his wrist and felt his pulse; it was forcible and regular. I was feeling it when it quite disappeared from under my finger, many beats being missed. I looked at him; he had become very pale in the face, twitching set it, and he at once went into a very severe epileptic convulsion." Moxon's house physician, Mr. Lane, corroborated the same fact twice on the same patient. Moxon noted a third example. "I was examining the heart of a young gentleman who was asking my advice on account of attacks of epilepsy. He was standing and I had my stethoscope over his heart and was attending to the quality of the sounds. These sounds stopped suddenly and so completely that in great surprise I moved to look at him and saw him with exceedingly pale face, evidently quite unconscious, his balance just lost and he falling forwards. He forthwith went into severe epileptiform convulsions. Dr. Hughlings Jackson has kindly informed me that he has observed on several occasions the pulse to disappear during the paleness of the face in the onset of attacks of *petit mal*." At the conclusion of his lecture Dr. Southey informed Moxon that in the only instance in which he had his finger on the pulse at the beginning of an epileptic convulsion he observed the pulse to disappear during the onset of the attack. Moxon further remarks that "I have found the pulse present again when the clonic spasms have just commenced." He attributed the cessation of the heart to the action of the pneumogastric nerve but recognised the fact that the cause of this pneumogastric impulse was yet to seek. Hilton Fagge[2] records a similar case. He was listening to the heart of an epileptic when it ceased to beat and the man fell back. Presently it recommenced to beat and then there was a little twitching of his hands.

---

[1] Moxon: On the Influence of the Circulation on the Nervous System, THE LANCET, April 23rd, 1881, p. 648.

Other similar cases are on record. Hare in his recent work[3] has revived the old idea that epilepsy is due to cerebral anæmia and has propounded the following statement as representing the sequence of events in the genesis of a fit: "I shall assume provisionally that in epilepsy, as in most of the paroxysmal neuroses, there is a widespread area of vaso-constriction tending to cause a rise in the general blood pressure; that this vaso-constriction whether because it is sudden or because it is very extensive leaves no *time or room for adequate compensation by an area of vaso-dilation*; and that consequently cardiac inhibition through the vagus is demanded to check the continuous rise in the general blood pressure so induced. So is occasioned a grave modification of the heart beat of the nature of slowing and weakening, amounting, perhaps, quite often to actual cessation. In this way are produced a more or less sudden fall in the blood pressure and a more or less sudden anæmia of the brain; and this is the proximate factor of the unconsciousness and of the convulsions. Synchronous with the initial rise of blood pressure are the various premonitory symptoms or auræ of the fit; synchronous with the sudden fall in blood pressure is the commencement of the unconsciousness and of the tonic muscular spasm; synchronous with the recommencing or accelerating heart beats and the consequent progressive recovery of the blood pressure is the relaxation of the tonic spasm and its substitution by intermittent or clonic convulsions presenting progressively widening intervals. As the blood pressure continues to rise the clonic convulsions become less and less frequent and finally cease."

It is perfectly true that such cardiac arrest is not a constant phenomenon in epilepsy. It is well known that the pulse may be maintained in fair volume throughout the whole fit and Gowers[4] states: "The pulse may be feeble at the onset but I have never noted an actual initial failure. It is generally unaffected at the commencement. A *tracing* published by Voisin shows that the heart's action may be perfectly normal *during* the stage of aura." But it is very possible that cardiac arrest in the onset of an epileptic fit may be much commoner than is suspected. It is obviously a matter of some difficulty to make observations as it is usually impossible to predict when a fit is likely to occur.

The phenomenon merits greater consideration than it has received. It is clear that cardiac arrest may precede the development of the fit and it is also well known that stoppage of the heart for a sufficient period will give rise to attacks of unconsciousness and convulsions, the so-called Stokes-Adams syndrome. A most remarkable case has been published by Webster,[5] of a man, aged 48 years, whose heart would intermit for periods varying from 10 to 20 seconds. The features observed in one of these periods of intermission were that so soon as the pulse became suspended the face became rapidly and extremely pale; later, after some 15 seconds of absence of pulse spasmodic twitchings of the muscles of the face were observed; as the period lengthened still further the spasmodic movements extended to the muscles of the neck and ultimately the arms and legs took part in the convulsive movements. During the more severe crises either concomitant squint of both eyes or conjugate deviation to either side was observed and the pupils became widely dilated. Respiration was noisy, with considerable puffing out of the cheeks, and froth appeared at the mouth. During the greater part of the period the patient was quite unconscious. Flushing of the face and return of consciousness were always almost simultaneous with the appearance of the pulse at the radial artery, the pulse being felt slightly before the flushing of the face was observed. Webster's paper is accompanied by a series of 60 beautiful sphygmograms which establish beyond question that the arrest of the heart preceded the epileptiform attack. Another very instructive case has been published by J. M. Finny.[6]

The efficacy of cerebral anæmia as a means of producing unconsciousness and convulsions scarcely requires mention. The well-known experiments of Kussmaul and Tenner and the effects of a rapid and severe hæmorrhage in man may be just mentioned. No cause could be more potent than a sudden cessation of the beating of the heart for the production of an anæmia not only of the brain but of the medulla, cord, and entire body. It would account for the unconsciousness and it is beyond dispute that it can produce convulsions; it would act as the "physiological fulminate" of Hughlings Jackson.

Sudden cessation of the heart can certainly cause tonic spasm, as recorded in a case of sudden death due to vagus inhibition of the heart reported by me.[7] The clonic spasms are more difficult of explanation. According to Hare they may be due to the return of the blood to the brain and in this connexion a case reported by W. Broadbent[8] is worthy of note. The patient was a woman, aged 44 years, with double mitral disease, who for seven years had been subject to epileptic fits. One evening "she was sitting talking to her daughter when she was suddenly unable to speak plainly and became rigid preparatory to a fit. Her daughter stated that instead of the usual fit there was irregular jerking of the right arm and leg and the mouth was drawn over to the right, but she says the head was turned to the left; the left arm and the left leg remained absolutely passive. She passed water during the fit." She was unconscious for five hours after the fit and was then found to have left hemiplegia and hemianæsthesia. Death occurred on the ninth day. Post mortem, in the right middle cerebral artery just beyond the point of origin a small embolus was found with a distal thrombus for half an inch. There was extreme softening both of the cortex and of the basal ganglia of the right side of the brain.

The case is recorded as one of cerebral embolism occurring just at the commencement of an epileptic fit; but whether that was so or whether the embolus initiated the attack is difficult of proof. Cerebral embolism is not infrequently associated with convulsions and occurring in an epileptic it would presumably be still more likely to precipitate a fit. If in this particular patient the fits were associated with cardiac arrest, the extremely interesting point arises that the embolus would prevent any return of blood to the right side of the brain. The case therefore affords support to the theory that the clonic convulsions are due to the returning blood flow.

The fact that a powerful mechanism for producing cardiac inhibition does exist in the vagus nerve and in its connexions would be sufficient to account for the cardiac arrest that occurs in certain cases of epilepsy. If such mechanism were unduly sensitive or if the ordinary causes which induce vagus inhibition of the heart (such as a rise in blood pressure) were either abnormal or excessive, then cardiac inhibition might occur with undue ease and frequency. It might be urged that stoppage of the heart is a serious event and that if it occurred frequently there would be some probability of its bringing about the death of the patient. But it is a fundamental physiological fact that under experimental stimulation of the vagus there is a practically irresistible tendency for the heart to recommence beating, even during the stimulation—the so-called vagus escape of the heart. This vagus escape of the heart would account for the recovery from the fits. It is not contended that vagus inhibition of the heart occurs as an initial factor in every epileptic fit. Any cause competent to produce a sudden or rapid cerebral anæmia might be equally efficient and in this connexion it may be remembered that vaso-constriction of the cerebral arteries has been advanced in the past as the cause of epilepsy. This hypothesis has been discredited but the recent demonstration of nerve fibres in the cerebral vessels and other evidence of vaso-motor activity in the brain give considerable food for thought.

The phenomena of Raynaud's disease find adequate explanation in extreme vaso-constriction occurring in the affected parts. The cerebral complications which occasionally occur are explicable on the grounds that a similar *constriction* occurs in the cerebral vessels. Thus Osler[9] records the case of a woman, aged 48 years, who was subject to the ordinary phenomena of Raynaud's disease but in addition she had three attacks of aphasia with partial right hemiplegia occurring with the attacks of Raynaud's disease and one of left-sided weakness. These were transient and in each case followed by perfect recovery. That the retinal artery may be narrowed with impairment of vision is also known to occur in Raynaud's disease. Such phenomena strongly favour the view that the cerebral arteries, like those in other situations, are subject to variations in their calibre. It is very interesting, moreover, to note that Raynaud's disease is apt to be associated with epileptic fits and, indeed, Monro[10] states that 5 per cent. of cases of Raynaud's disease have suffered from convulsions at some time or other and several very striking cases of the association are on record. Thomas and Osler[11] record the case of a man whose attacks of Raynaud's disease were associated with severe epileptic attacks. The sequence of events was as follows. Firstly, the fingers became cold, white and dead, and the nails blue, associated with considerable pain. Then followed general chilliness with cold feet. These premonitory symptoms lasted for five minutes and were succeeded by unconsciousness and convulsions lasting for half an hour. In this case there was, firstly, the arterial spasm leading to the local syncope of the fingers; and secondly, general chilliness probably to be attributed to a general cutaneous vaso-constriction. The resulting rise of blood pressure on Hare's hypothesis would be the factor determining the vagus inhibition of the heart. The convulsions might also be explained by a vaso constriction affecting the cerebral vessels, the occurrence of which in cases of Raynaud's disease has been suggested above. Other cases illustrating the association of epilepsy and Raynaud's disease are also on record. Harvey Cushing[12] notes that, "contrary to the positive statements of many, substances like epinephrin will blanch the pial vessels over the area of its application, as will occasionally a jet of cold water against the brain or the faradic current used for cortical stimulation."

This short paper has been written to point out that cardiac arrest does occur in some cases of epilepsy and to suggest that such arrest may be far commoner than is suspected. If observations were made on the pulse at the onset of fits by those whose work brings them into contact with epileptic patients in considerable numbers it would soon be established whether such cardiac arrest be of occasional or of frequent occurrence. Sudden cerebral anæmia due to cardiac inhibition (or to cerebral vaso-motor spasm) would account for most of the symptoms of an epileptic fit and it is suggested that the recovery from the fits finds adequate explanation in the well-known physiological fact—the vagus escape of the heart. Certain morbid changes have been described in the brains of epileptics but it is at least possible that they may be secondary to the repeated attacks of transient cerebral anæmia which must follow cardiac arrest and to the extreme congestion of the brain that the convulsive movements give rise to. Even if cardiac arrest can be proved to have no etiological influence in the mechanism of an attack it is worthy of study and is a symptom of great clinical importance, but it would be singular if a condition which in itself is competent to produce an epileptic fit were merely a side issue in the course of an attack.

NOTES OF TWO CASES OF AMPUTATION OF THE SHOULDER-GIRDLE.[1]

By J. CRAWFORD RENTON, M.D. Edin.,
SURGEON AND LECTURER ON CLINICAL SURGERY AT THE WESTERN INFIRMARY, GLASGOW; EXAMINER IN SURGERY AND CLINICAL SURGERY IN THE UNIVERSITY OF ABERDEEN.

Case 1.—The patient, a man, aged 40 years, was sent to me by Dr. A. N. Montgomery and was admitted to the Western Infirmary in December, 1900, suffering from an ulcer over the right forearm. There was a history of syphilis and the patient stated that he had had a nodule on the arm for 14 years. A portion of the ulcer was removed and was found on examination by Dr. A. R. Ferguson to be an epithelioma. His arm was amputated in the middle of the upper arm. In April, 1903, the disease recurred in the stump. The rest of the arm was disarticulated at the shoulder-joint and the growth was then found to look like a spindle-celled sarcoma, which is a point of considerable interest and which will be referred to later. On Feb. 10th, 1906, the patient returned with a recurrence, the whole stump and axilla being occupied by a very large tumour. Removal of the tumour was recommended and on the 19th the clavicle was divided at its inner third, the subclavian artery and vein were tied, and the tumour along with the scapula and two-thirds of the clavicle and an additional growth on the side of the chest were removed. By adopting this method, recommended by Berger, there was practically almost no bleeding, a few intercostal branches being easily secured as they were divided. The patient suffered from very little shock and made an excellent recovery. Stereoscopic photographs showed the condition previously to, and after, operation, as also the appearance of the patient with an artificial arm applied.

Report by Dr. M. Logan Taylor.—On dissection of the stump, which was removed along with the scapula and the outer half of the clavicle, a large tumour mass is found occupying the original position of the head of the humerus and extending down the axillary border of the scapula to its inferior angle. In this tumour mass are involved practically all the muscles about the shoulder joint, the deltoid especially being inseparable from it. The cut ends of the axillary vessels and of the brachial plexus of nerves run right into the centre of the growth. Microscopical examination of this second recurrence shows it to be a carcinoma. At first sight it has not got just the typical appearance of a squamous-celled epithelioma, but closer examination of the tumour cells shows them to be undoubtedly epithelial cells of the squamous type. The stroma is very well developed; alveoli are numerous and are filled with epithelial cells which in many instances are undergoing mucoid degeneration.

The primary growth was reported by Dr. Ferguson as being a squamous epithelioma, the first recurrence by Dr. J H. Teacher (April, 1903) as being a spindle-celled sarcoma, though he was aware at the time of the primary growth being a cancer, and now this second recurrence turns out to be epithelioma. Unfortunately the sections of the previous growths have not been kept, so it is impossible to refer to them now. Dr Teacher thinks that the first recurrence may have been a cancer after all but closely simulating a sarcoma.

Case 2.—The patient, a woman, aged 60 years, was sent to me by Dr. M. T Mackenzie of Scolpaig and was admitted to the Western Infirmary on Feb. 23rd, 1906. Two years ago she had hysterectomy performed for uterine fibroid by Professor Murdoch Cameron. She now suffered from a large tumour involving the upper part of the right humerus which was broken. The circumference of the arm was 14½ inches, as compared with 12 inches on the opposite side. The tumour had extended so much into the axilla and had pushed up the supraclavicular space that anything short of a shoulder girdle amputation was impossible. This was carried out exactly as is above described. There was very little shock and the patient went home on March 19th.

Report by Dr. Taylor.—The growth in the humerus is a large one, measuring 6 × 3½ × 3 inches. It extends from the anatomical neck of the humerus to the middle of the shaft. It is now impossible to say whether it has been originally a central or a periosteal growth for the tumour has completely replaced the shaft in the part affected. The articular surface of the head of the bone is seen at the upper end of the tumour but it is comparatively loose and could be easily torn away from the growth. The distal half of the humerus after removal of all the muscles was found to be attached to the lower end of the growth quite loosely by some tumour tissue. The muscles about the shoulder were adherent to the growth but were involved to a slight degree only. Microscopical examination shows the growth to be a sarcoma of the mixed-cell type, the majority of the cells being small round ones; the others are short spindles.

---

[1] A paper read before the Glasgow Pathological and Clinical Society.

Remarks.—The two cases above described were operated on within ten days of each other and they illustrate the great value of Berger's amputation. By carrying out his method the mortality is practically the same as amputation at the shoulder-joint, which is extremely small. There was no special difficulty with either operation except in the woman, where it was a little more troublesome to expose the subclavian artery and vein owing to her stoutness and the size of the tumour. I have great pleasure in strongly recommending the operation.

Glasgow.

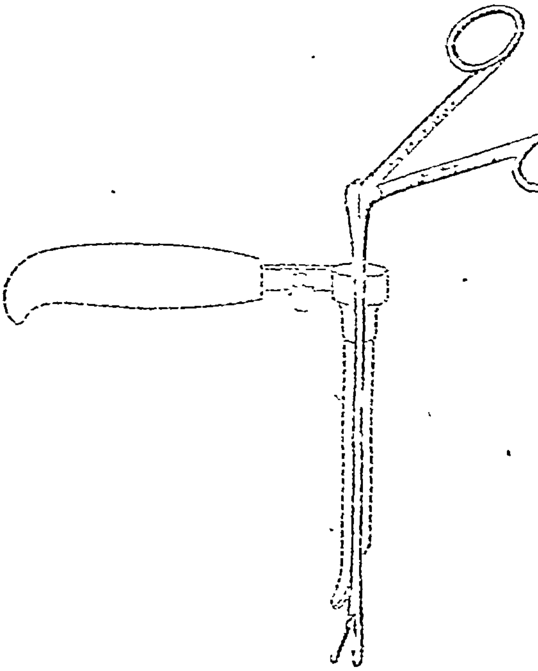
THE OPERATIVE TREATMENT OF LARYNGEAL PAPILLOMATA IN CHILDREN.

BY D. R. PATERSON, M.D. EDIN.,
SURGEON TO THE EAR, NOSE, AND THROAT DEPARTMENT, CARDIFF INFIRMARY.

THE frequency with which papers appear upon this subject is an indication of the difficulties which surround it and of the unsatisfactory nature of the results. Its importance, however, should not be under estimated as the frequent recurrence of these growths, even after what appears to be complete removal, is a constant menace to the life of the child. Of the three methods of treatment generally practised the operation of thyrotomy has been advocated on the ground that it permits of a more thorough clearance of the larynx. It exposes the parts completely and enables the operator to curette away all the affected tissue. Many objections have, however, been urged against it. Apart from the ordinary risks incidental to external cutting operations on the air passages, which are by no means insignificant, injury to the voice has resulted in not a few instances. Moreover, it does not guard against recurrence, however completely it may be done, and repetition of the operation may be necessary. Many cases are recorded of recurrence after thyrotomy and in one instance this operation was performed on a child as many as 17 times within two years.

Another mode of treatment—the performance of tracheotomy—is often a matter of urgency. Some authorities advise postponing any operation until the patient is older, unless, of course, obstruction of breathing supervenes. Insertion of a cannula in the trachea insures rest to the glottis for a prolonged period and has been followed by good results in many cases. It is necessary, however, to retain the tube for a considerable time, from 18 months to two years, and this cannot be regarded as a measure without some risk. I have on one occasion seen disappearance of the papillomata after a tube had been worn for that period but in others it had to be supplemented by the third or endolaryngeal method. This procedure, which is the one usually adopted by laryngologists, is an attempt to remove the growths by the natural passages. In order to control it, the use of the laryngoscope is necessary but the difficulties with this instrument in young children are so great that it is sometimes impossible even to get a satisfactory view of the larynx. For some years I used this method in the manner generally adopted, with the child under a general anæsthetic combined with local anæsthesia. The little patient, placed sitting in the nurse's lap, has chloroform administered in that position. Several assistants are required. A solution of cocaine brushed on the pharynx and larynx enables the instruments to be used without exciting reflex action, but great difficulty is experienced in keeping the part free from the copious secretion of mucus. I generally employed Mackenzie's spoon-blade forceps and for the smaller pieces Schroeter's instrument which could be moulded to fit into recesses. This procedure is of course very difficult to carry out in young children and in many cases it is impossible to thoroughly clear the larynx. Still, in a few cases excellent results were obtained, but the difficulty of clearing the anterior commissure and subglottic space is so great that recurrence is frequent and the operation has to be repeated. Some operators abandon the laryngoscope and are content to be guided solely by the sense of touch. Here the patient is placed on the back on a table under a general anæsthetic, but even with guarded instruments this procedure is not without risk of damaging the larynx. I have several times adopted it but have rarely succeeded in effecting a good clearance. Though these difficulties stand in the way of the general adoption of the endolaryngeal method there is no question that it should be tried in the first instance as it involves less risk to life and to the voice. This can be more strongly urged at the present time as the drawbacks I have enumerated are almost entirely got rid of by employing the direct method of examining the larynx. The ease with which the larynx can now be brought under inspection and the excellent view of the field of operation which may be obtained have much simplified endolaryngeal procedure and rendered it more effective. The advantages of this method are great and it is the purpose of this short paper to draw attention to them as illustrated by my own experience.

The introduction in 1895 by Kirstein of the autoscope marked a real advance in the direct examination of the larynx. His "universal spatula" I found very serviceable for inspection of the larynx though the amount of pressure that had to be exerted in order to depress the tongue made it in certain cases difficult to manipulate. To overcome this Killian employed a tube spatula and this improvement has greatly simplified the procedure and rendered it easier to carry out.



The instruments required for the removal of papillomata by the direct method are a fish-tail tube spatula with handle attached and a straight forceps. The best form of illumination is the Kirstein electric head lamp which has very good illuminating power. The operating table should be of sufficient height to enable the operator when seated on a low chair to work conveniently. If the table be too low he has to assume a cramped uncomfortable position in which the light is uncertain and the instruments are difficult to manage with ease and precision. The patient should be placed on the back with the head hanging over the end of the table and a low pillow under the shoulders Chloroform is the most suitable anæsthetic to administer and full anæsthesia can be easily kept up from a Juncker's inhaler with the mouth-tube hooked round the angle of the mouth. The pharynx is brushed lightly with a 10 per cent. solution of cocaine, the tube spatula is introduced, and through it the entrance of the larynx and the under surface of the epiglottis are similarly brushed. A few drops of adrenalin may be added to the cocaine solution as it prolongs the anæsthesia and prevents hæmorrhage during the operation. The difficulty with the mucous secretion is comparatively slight in this position as it drains into the most dependent part of the pharynx. Very little chloroform is required to maintain the general anæsthesia, a matter of some comfort to the operator as the expired chloroform coming out in a jet through the tube spatula impinges on his eye, causing smarting and interfering with the proper view of the parts. In the introduction of the spatula its point is passed along the under surface of the epiglottis and then tilted upwards so that it carries that structure forwards and enables an admirable view of the larynx to be obtained. In the majority of cases even this is not necessary. Placing the fish-tail end of the spatula on the base of the tongue immediately in front of the epiglottis and exerting pressure forwards is quite sufficient to bring the interior of the larynx into full view, and the whole of the operation can be carried out with the spatula in that position. For the removal of the papillomata I have employed various forms of forceps and after several trials I have had constructed by Messrs. Mayer and Meltzer one that I find very serviceable (*vide* illustration). It is a forceps with a straight shank fashioned on the crocodile principle and terminating in a beak with cutting edges. From the bend on the shank to the tip the length is nearly eight inches. It is used through the tube spatula and is lightly built so as to interfere with the view as little as possible. At the same time it is capable of dealing with fairly tough tissue. Various forms of beaks have been constructed to fit into the different parts of the larynx.

In operating the forceps is introduced through the spatula and the pieces are grasped and removed. If it is done rapidly the larynx can be fairly cleared before hæmorrhage shows itself to any extent. This is never very prominent and the head being dependent it runs into the pharynx where it can be mopped up. The two parts of the larynx which are most difficult to get at are the anterior commissure and the subglottic space. It is here that recurrence is most apt to take place, as the removal is generally imperfect. In one case the recurrence was eventually limited to the region of the anterior commissure. The beak of the straight forceps can be inserted into this space and a more complete clearance effected. It is more difficult to deal with the subglottic area, as the surface is more flat and the projecting masses are not so easy to grasp. The narrow-beaked forceps have been found very serviceable here and their use may be supplemented by a curette. For this purpose I have employed a modification of Löri's curette. This instrument has a receptacle to catch the detached pieces of growth and prevent their being aspirated into the air passages and has terminals of different calibre to suit various sizes of larynx. I have had the instrument adapted to the direct method by using a shank similar to that of the forceps. As it cuts from below upwards it is passed beyond the part to be removed and, pressed firmly against the tissue, it is drawn with a firm stroke upwards. As the cutting edge can be adapted to any part of the interior of the larynx any remaining papillomata can be dealt with effectually. As the larynx of the child is capable of considerable lateral displacement it is of much help to have the organ steadied from outside by an assistant. Much greater pressure can then be exerted, notably where the papillomata are sessile and tough. The endolaryngeal operation carried out by the direct method has given such excellent results that I have no hesitation in urging its adoption in the first instance in all cases of laryngeal papillomata. Where recurrence takes place soon and is persistent I would advise in addition the wearing of a tracheotomy tube for a time. This has a distinctly good effect in retarding the growth and enables the operator to deal more thoroughly with the papillomata at each sitting.

Cardiff.

PAIGNTON (DEVON) COTTAGE HOSPITAL.—The committee of the Paignton Cottage Hospital has decided to erect a new operating theatre and to provide extra accommodation for the administrative block. The cost of the undertaking has been estimated at £1172 and the work is to be commenced shortly.

A CASE OF CONGENITAL ABNORMALITY OF THE GENITO-URINARY ORGANS.

BY G. F. DARWALL SMITH, M.B., B.CH. OXON., F.R.C.S. ENG.,
OBSTETRIC TUTOR AND REGISTRAR TO ST. GEORGE'S HOSPITAL;
AND
A. LIONEL H. SMITH, M.R.C.S. ENG., L.R.C.P. LOND.,
REGISTRAR TO THE GENERAL LYING-IN HOSPITAL.

THE following case seems sufficiently uncommon to deserve publication.

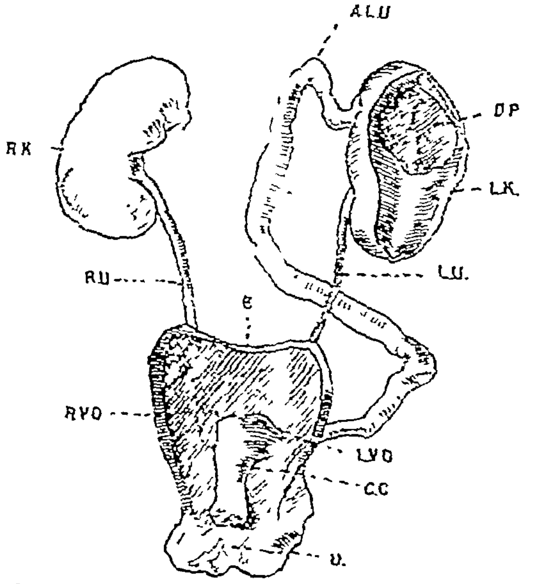
Clinical description.—The patient, a female infant, was first seen by one of us on Oct. 6th, 1905. She was then five days old. Her mother had been attended at her confinement by a very experienced and highly skilled midwife who is an inspector of midwives under the Central Midwives Board. This midwife reported that at birth the child presented no external abnormality and that the labour had been normal in every respect but that on the fourth day the condition immediately to be described was first seen. On the fifth day when seen by one of us this condition was as follows. A dark red globular swelling of the size of a walnut was protruding from the vulva. On its surface were a few darker hæmorrhagic patches and a little blood was oozing from it. The swelling was thoroughly bathed with boric acid lotion and was examined further under full antiseptic precautions. It was then found to be protruding from the urethra. The orifice of the vagina, which appeared quite normal, was posterior to it and behind this again there was slight prolapse of the rectal mucous membrane. The swelling felt cystic and rather thin-walled but was not particularly tense. It did not seem to be tender when handled gently and gave no impulse to the hand when the child cried. On the right side near its base one ureteric orifice could be seen from which a little urine spurted gently at intervals. The left side showed more congestion than the right but no ureteric orifice could be found here, although urine appeared to well up on this side also. The swelling was not at all tightly gripped by the urethral orifice. Several attempts were then made to compress and reduce the swelling back through the urethra with the fingers but as these were unsuccessful a blunt probe was used very gently to push it up by degrees, starting from its base. On one occasion while this was being done, in spite of great gentleness the probe felt as though it had pierced the wall of the swelling; there was, however, no gush of fluid from the puncture (if puncture there was) nor was there any appreciable decrease in size of the protrusion. However, after this the probe was laid aside and replacement was finally effected by passing the whole of the little finger up the urethra, through which the finger passed with extraordinary ease. The reduction did not seem to cause any pain. The child appeared perfectly well and there was no history that she had been ailing in any way. Neither abdominal nor rectal examination disclosed anything abnormal and no cause for straining could be discovered elsewhere.

The diagnosis seemed to lie between inversion of the whole bladder wall, inversion of the mucous membrane of the bladder, and prolapse of a "ureteric cyst," together with part of the bladder. Inversion of the whole bladder wall seemed improbable owing to the apparent thinness of the walls of the swelling and owing to the absence of any impulse on crying, while the absence of any discoverable ureteric orifice on the left side seemed to point to some possible connexion between the swelling and the left ureter. The swelling had not the funnel-shaped appearance which is described as being characteristic of prolapse of the ureter. As the child appeared perfectly well it seemed best to watch the case for the present. Accordingly a pad of aseptic wool was applied to the vulva, cleansing of the vulva with boric acid lotion at frequent intervals was ordered, and dilute boric acid ointment was applied to the skin in the neighbourhood.

It may be mentioned that the child had two elder brothers who were said to be normal in every respect and her parents similarly denied any abnormality of their persons. During the night of Oct. 6th the swelling again came down but was much smaller than before. It was also now rather darker in colour and quite flaccid. There was no sign of any sloughing or infection of its surface. It was replaced as before. During the next 24 hours it was replaced three times but each time that it came down it was smaller than when last seen. The child remained quite happy and well.

On the 8th the swelling only appeared once and was distinctly smaller. It did not appear again until the 10th, when it was only of about the size of a large pea. On the 13th it appeared and was replaced for the last time, and on this occasion it was noticed that the vesical sphincter was distinctly tighter than it had been hitherto. The child throughout seemed very well and contented and between the 8th and 14th had gained six and a half ounces in weight, in spite of a change from the breast to bottle feeding. On the 15th she suddenly had a convulsion during which she died. The cause of the convulsion was not obvious.

Pathological description.—A necropsy was performed about 12 hours after death. Rigor mortis was fairly well marked. Post-mortem hypostatic congestion was present over the most dependent parts. The buttocks were not sore. The hands were tightly clenched and the lips were almost black. The general appearance of the cadaver was strongly suggestive of death from asphyxia. The body was rather small but well nourished and the amount of subcutaneous fat was normal. An incision was made in the middle line from the chin to a little above the umbilicus. Thence it was carried slightly on the left to the pubes so as to avoid injury to the urachus.



Semi-diagrammatic representation of the parts in a case of congenital abnormality of the genito-urinary organs. B., Bladder. U., Urethra. R.K., Right kidney. R.U., Right ureter. R.V.O., Vesical orifice of right ureter. A.L.U., Accessory left ureter. D.P., Dilated pelvis to left accessory ureter. L.K., Left kidney. L.U., Left ureter. L.V.O., Vesical orifice of left ureter. C.C., Collapsed ureteric cyst.

The thorax: There was no fluid in either pleural cavity. Scattered over the surface of each lung were a few small subpleural hæmorrhages, varying in size from that of a pin's head to that of a millet seed. On section the lungs were found to be normal, except that they were rather engorged. There was no excess of fluid in the pericardium. Scattered over the surface of the heart were a few subpericardial hæmorrhages similar to those found on the lungs. In other respects the heart was normal. The thymus seemed rather smaller than usual. The larynx, trachea, and bronchi were normal.

The abdomen: There was no fluid in the peritoneal cavity. The liver was normal. The spleen was rather smaller than usual but was otherwise normal. The pelvic colon entered the pelvis on the right side, its usual situation being occupied by a coiled tube similar in size and appearance to the rectum but obviously having no connexion with the intestine. The ovaries and Fallopian tubes were lying on the dorsal abdominal wall, reaching as high up as, and intimately attached to, the inferior end of either kidney. On the left side of the abdomen beneath the peritoneum was a tortuous tube very similar in size and appearance to the colon, for which it was at first sight mistaken. This, however, on further dissection was found to be a very much dilated accessory ureter. The whole length of the intestine from the stomach to the end of the rectum was removed. It was found to be normal. The pelvis was split through the symphysis and the two halves were widely separated. The vagina, rectum, bladder, uterus, Fallopian tubes, ovaries, ureters, and kidneys were removed *en masse*. The brain also was examined but nothing abnormal was found.

Detailed description of the genito-urinary organs.—The right kidney was normal in size and appearance; on section it presented no abnormality. The right ureter was normal and measured two and a half inches in length. The ovaries and Fallopian tubes, which were lying on the dorsal abdominal wall, were attached to the perinephritic tissue at the lower end of the kidneys. The left kidney was slightly larger than the right. Scattered over its surface at the upper end were a few small, tense cysts. Two ureters arose from the hilum (see figure), the lower one being normal, the upper and larger one arising from a largely dilated pelvis, distinct from the pelvis belonging to the lower ureter. On section the upper end of the left kidney was found to be completely occupied by the dilated end of the accessory ureter with the exception of the thinned-out cortex, which measured no more than one-eighth of an inch in thickness. The wall of this dilatation was quite smooth and showed no trace of pyramids nor of the openings of the ducts of Bellini to the naked eye. The accessory ureter and its dilated upper end were filled with a pale yellowish and slightly opalescent fluid. The smaller and lower left ureter opened into the lower end of the kidney in a normal manner. The pelvis was small and had about a dozen pyramids projecting into it. The smaller left ureter measured three inches in length and was therefore slightly longer than its fellow of the opposite side. Its diameter was approximately the same as that of the right ureter. The accessory and upper left ureter, which was extremely tortuous, measured six and a quarter inches in length and seven-twelfths of an inch in diameter when flattened out. Where it passed through the bladder wall it was much constricted. It entered the bladder below the opening of the smaller left ureter which opened at the upper limit of the wall of what was apparently a collapsed cyst formed by the lower end of the accessory ureter. The bladder was slightly larger than normal and at the fundus presented no obvious abnormality except that the mucous membrane had a few hæmorrhagic spots upon its surface. Projecting from the left side of the region of the trigone was a pink, thin-walled, pear-shaped, and collapsed cyst, the apex of which passed out through the urethra and probably terminated originally at the vulva in the cystic swelling described above. A fine probe could be passed with difficulty from the interior of the cyst through the constricted part of the ureter which lay in the bladder wall into the dilated accessory ureter above. The smaller left ureter opened at the upper limit of the cyst wall close to its origin from the bladder wall and very near to that margin which was nearest to the middle line of the body. The opening of the right ureter was situated on the posterior bladder wall on a level with the upper border of the cyst and slightly to the right of it. The urethra was dilated but was otherwise normal. The uterus was normal. The ovaries and Fallopian tubes were normal except as regards their position and attachments on the posterior abdominal wall. The vagina and the labia minora and majora were all normal. Microscopic examination of part of the cyst wall showed normal transitional epithelium on its vesical surface and very much thinned and flattened epithelium of the same character on its ureteric surface. Between these two layers of epithelium was some very vascular connective tissue which did not appear to contain any muscle fibres.

Remarks.—In the light of the necropsy it seems probable that this was a case of a dilated accessory ureter either with a blind cystic ending in the bladder wall or with ballooning of its lower end due to congenital narrowing of its orifice. Which of the two it really was it does not seem possible to say now. The treatment pursued in this particular case was dictated by the marked and progressive decrease in size of the protruded swelling and by the total absence of any morbid signs or symptoms exhibited by the child with the exception of the protrusion. Had the condition of the accessory left ureter been ascertained before death, doubtless it would have been better to have made a free communication between the bladder and the cyst, but even as it was the cyst apparently collapsed and the ureter did not, so that probably that treatment would have failed also. It is noteworthy that the thin-walled, pearl-grey appearance of the swelling, which is said to be present often in the case of these so called ureteric cysts, was entirely absent in this case.

MICROSCOPICAL AND CHEMICAL OBSERVATIONS ON A CASE OF SCLEREMA NEONATORUM.[1]

BY GEORGE CARPENTER, M.D. LOND., M.R.C.P. LOND.,
PHYSICIAN TO THE NORTH-EASTERN HOSPITAL FOR CHILDREN AND MEMBRE CORRESPONDANT DE LA SOCIÉTÉ DE PÉDIATRIE DE PARIS;

AND

SHEFFIELD NEAVE, B.A. OXON., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE NORTH-EASTERN HOSPITAL FOR CHILDREN.

THIS disease is not often met with, and less often in England than on the continent. Its favourite localities appear to be in Italy and France. It has been confounded in text-books with œdema neonatorum but it is quite distinct and there is no difficulty in diagnosing between the two. There are nevertheless two disorders, differing at any rate in degree, which both go under this name. The first, by far the commoner in this country, attacks otherwise healthy children of normal term at birth and is practically confined to the skin and the subjacent structures, usually ending in recovery at about six months; while the second, which is more usually found on the continent, attacks weaklings often of premature birth, and is a severe malady with serious constitutional symptoms of the alimentary and respiratory systems as well as of the kidney and is very fatal.[2] The case about to be described is of the first-mentioned order.

The patient was admitted to hospital on Dec. 30th, 1905, being six weeks old, well nourished, with normal temperature, and in fact normal in every way except for the induration of the skin on the posterior aspect of the body. The skin so affected was of a pink, purplish appearance and of a less even outline than usual, having some well marked dimples and rounded but slight eminences. On applying pressure with the finger and then removing it no pitting occurred, but the colour faded to white and slowly returned as the effect of the finger pressure passed off. When the skin was pinched up between the finger and thumb the underlying tissue being closely adherent appeared when doubled together to keep the fingers more than one inch apart and gave a sensation as if a layer of indiarubber were adherent to the under surface of the skin. This kind of induration extended all over the back and buttocks, the back of the neck and lower part of the back of the scalp, the back of the arms and deltoid regions, and the back of the thighs. In the last-mentioned region it tapered to a point just above the back of the knee in a very characteristic way. The edges of the indurated areas terminated by gradually thinning. Later these signs extended slowly and to a less degree to the angles of the jaws, the sides of the neck, down the arms nearly to the wrist, and there were islets formed all over the abdomen and chest. Pain was never an accompaniment of these indurations. During the five months the child has been under observation, although the above extensions took place, these signs have cleared up irregularly but continuously. At the time of writing a small triangular patch of induration exists between the shoulders with the apex downwards on the spine, but it is not nearly so thick or hard as in the first place. There are a small patch on the right buttock and an islet on the right cheek just below the superior maxilla. The glands are somewhat enlarged and shotty in the posterior triangle of the neck and in the groin and the spleen reaches one finger's breadth below the ribs. Throughout there was nothing distinctive taking place in respect of the temperature. A blood count was made but gave nothing very definite—viz., polymorphs, 34; lymphocytes, 57·5; large mononuclears, 0·6; myelocytes, 0·5; and eosinophiles, 2; total, 100; erythrocytes, 4,212,000; and leucocytes, 22,500. The child has during her stay in the hospital thrived very satisfactorily and the skin has cleared up as described under massage, together with, first, thyroid and then thymus extract given internally. The thyroid was first given for a month when some improvement was made. Thymus was then given, beginning with a small dose and being raised to 30 grains per diem, though subsequently reduced to half that amount. During this last treatment progress appeared to be much hastened.

A small piece of skin and subcutaneous tissue down to the muscle was excised by Mr. J. P. Lockhart Mummery from the back of the thigh for microscopical examination. Macroscopically, the fat and superficial fascia appeared to be perhaps thicker than usual but only slightly. The fat, however, was certainly whiter and in larger globules than usual and was much harder to the touch. Nothing further abnormal was, however, detected under the microscope, a control examination being made at the same time of a similar specimen of healthy skin from another child of the same age. The serous infiltration and increase of connective tissue mentioned in some cases were certainly absent and in this way this case agrees with that of Northrup mentioned by Holt.

The fat was submitted to Professor J. Addyman Gardner, M.A., F.I.C., for examination. He reported as follows:—

> I am afraid my investigations do not throw much light on the case. There were two difficulties which it was impossible to get over: (1) the small quantity of the sample, and (2) the fact that it was probably somewhat altered by the prolonged soaking in the formalin fluid. The dry specimen contained only 68 per cent. of fat, the rest being ordinary tissue matter, as far as could be determined in the dried residue after extraction, and this appears to agree with your microscopical report. The saponification equivalent was 205. The specimen also contained unsaturated fat—e.g., olein—but it was too small to permit of a quantitative estimation. The values usually given for the saponification equivalents of the various pure fats are: tripalmitin 209, tristearin 189, triolein 19 , horse fat 190·4. One might conclude from this that the specimen was particularly rich in palmitin. In the hope of throwing some light on the matter I examined the saponification equivalents of specimens of human fat cut from various parts of the body but they showed very considerable variation.
>
> I thought at first that the specimen of fat and the acids from it seemed more solid than is usual in human fat, but my examination of the specimen mentioned scarcely bears this out.
>
> On the whole, I am inclined to doubt whether the fat in the sample was in any way abnormal and think that the cause of the trouble must be sought in the associated matter.

It is thus obvious that the pathology of the disease is very obscure and it is hoped to call attention to the malady by the publication of this case, so that the work done here, although so negative, may be of some use to others as a starting-point for further investigation when new cases are obtainable.

A CASE OF ACTINOMYCOSIS.

PRIMARY ABSCESS OF THE LEFT LUNG EXHIBITING SPONTANEOUS CURE; METASTATIC MANIFESTATION IN THE PELVIS DECLARING ITSELF AFTER A YEAR'S LATENCY WITH ABSCESS FORMATION AND SLOW SPONTANEOUS CURE.

BY EDGAR TREVITHICK, M.D. CANTAB.

THIS illness occurred in a boy, aged 16 years, and has afforded a good example of a prolonged encounter between a living parasitic fungus on the one hand and human tissues on the other. If, as in this case, there now seems good reason to hope the tissues have ultimately succeeded in permanently stamping out the invasion they alone must be credited with the honours of the victory, for I have not been able to satisfy myself that any of the numerous artificial remedies that have been used have rendered any real assistance towards the patient's recovery.

There have been many points of interest observable in the course of this case of actinomycosis. It has illustrated in a marked degree the beneficent capabilities of rapid deposition of solid inflammatory exudation and has demonstrated with what great rapidity such exudation can be re-absorbed when its presence is no longer of service. It exemplifies the fact that a parasite may exist somewhere in the body for many months without showing any obvious signs of its whereabouts and that it may, after long periods of latency, declare its presence by stimulating violent and extensive tissue resentment.

One is tempted to suspect that during the long interval that elapsed in this case between the obsolescence of the original pulmonary lesion and the subsequent breaking-out of the secondary manifestation in the pelvis, obscure internal evolutions of some sort may have been taking place without giving rise to any gross manifestations. The condition of the patient's blood rather favoured such a view. For at the very outset of the second attack there was already marked leucocytosis and in addition great excess of extracellular bodies. And it is interesting to wonder along what path the parasite passed in its slow transit from one part of the body to another. The rapid fluctuations of body weight exhibited by the patient during the illness were very striking and the rapid spontaneous cure of the fæcal fistula that resulted in the course of the contest is also of interest.

---

[1] The case was exhibited at the Society for the Study of Disease in Children on Jan. 19th, 1906, and the observations herein recorded were conducted subsequently.

[2] Dr. A. M. Gray, the resident medical officer, has searched the records of the North-Eastern Hospital for Children for the past ten years and could find no mention of a case similar to the one about to be reported during that period of time.

History of the pulmonary attack.—When first seen on Oct. 19th, 1903, the boy was very wasted, had marked hectic flush, and complained of shortness of breath. He had been employed in "carrying milk from the farm to the village" and had "caught cold," he thought, *three months previously*. Even since that time he had been getting thinner and losing strength and just recently he had suffered from troublesome dry cough, loss of appetite, and diarrhœa. There had been no expectoration but his friends "had noticed a very curious odour about his breath." On examination I found evidence of extensive consolidation in the lower lobe of the left lung and I, too, was struck by the curious odour of the breath. *On Oct. 26th the patient began to* cough up very large quantities of offensive pus, the odour of which resembled that previously remarked in the breath. With the onset of this copious expectoration the general condition began rapidly to improve. A few days later the physical signs indicated the existence of a cavity about the centre of the lower lobe of the left lung, surrounded by a broad zone of consolidation. By Nov. 13th the cough and expectoration were very much less and the latter was no longer offensive. The boy went to a convalescent home on Nov. 30th, weighing stones 7 pounds, having gained 21 pounds in body weight in 27 days. And later he went back to his own home in the country as "cured" and was written down as having suffered from "abscess of left lung."

It must be confessed that at this stage of the illness no diagnosis of actinomycosis was made. The characteristic yellow bodies which were so plentiful in the discharges *from* the subsequent pelvic lesions were not noticed in the sputum. They were not, indeed, either thought of or sought for. But certain observations that were written down at the time, taken together with the study of the subsequent course of the case, make it, I think, certain that this pulmonary abscess was in reality caused by the same organism as later asserted itself in another part of the body.

A note written on Oct. 24th, 1903, describes the sputum as follows: "Very offensive, with singular odour. Shreddy, making films that stain badly and *seem* to contain fatty material. No tubercle bacilli, but swarming with very fine hair-like streptococci showing curious tendency to interlace into tangles." This was a clumsy description but a sketch I made at the time showing the organism, together with my recollection, makes me certain that the "very fine hair-like streptococcus" was in reality derived from actinomyces and makes it probable that the yellow characteristic bodies, although overlooked, may yet have been present. *It is* not improbable that ordinary clinical observation is easily capable of overlooking their presence in sputum; indeed, this case has led me to reflect about certain other cases of "pneumonia" that have from time to time presented puzzling features and yielded puzzling *sputa*. I suspect that even in hospital practice the term "pneumonia" as sometimes used is more convenient than scientific.

History of the secondary attack.—After about a year's "perfectly good health" the boy came back *complaining* of pain in his left flank and exhibiting a very hard craggy lump firmly attached to the brim of the pelvis. From Oct. 26th, 1904, to Sept. 28th, 1905, he was ill in bed and during this year he passed through many vicissitudes of illness, being more than once seemingly at death's door. The body weight in September, 1904, had been 8 stones 2 pounds and this gradually decreased until on April 3rd, 1905, it was 6 stones 4 pounds. At this latter date there was very extensive involvement of the lower part of the abdomen. The infested areas were obstinately and lavishly circumscribed by very extensive barriers of solid inflammatory exudation, which eventually reached as high as the level of the umbilicus. This abdominal contest was accompanied by irregular and sometimes very high pyrexia and led to the formation of two separate intra-peritoneal abscesses, one *of* which eventually communicated with the large intestine. There was considerable enlargement of the spleen and the patient's troubles were much aggravated by pressure on nerves and bedsores. About this time it seemed as if recovery was very unlikely. In the end, however, the tissues, as had been the case in the original pulmonary attack, were victorious. On Oct. 2nd, 1905, the body weight had risen to 8 stones 12 pounds. The fæcal fistula had healed spontaneously. The discharge from the two abdominal issues was very greatly reduced and the intra-abdominal buttresses of seemingly solid tissue had all but disappeared. Since Nov. 1st, 1905, the patient had been at work as a baker and in June, 1906, when I saw him, he reported himself and looked in excellent health.

On the subject of treatment I have nothing much to say. The initial manifestation in the lung subsided and healed spontaneously. During the long activity of the subsequent pelvic manifestations many lines of treatment were tried. I was induced to give a long trial to the x rays. I thought their application increased the vascularity of the tissue in the neighbourhood of the issues. Iodide of potassium seemed to me to have no effect.

Bacteriological considerations.—The yellowish bodies characteristic of actinomycosis were abundant for several months in the purulent discharge obtained from the intra-abdominal lesions. They were examined by several pathologists who all agreed as to their nature. When one of these bodies, after having been cleansed in sterile salt solution, was incubated in broth a very copious yellowish deposit always formed round it at the bottom of the tube in the course of a few days. And microscopically this deposit, in addition to containing masses of finely divided parts, was always rich in elongated hair-like filaments. Three different observers failed to obtain cultures from it on the surface of solid media. It was injected subcutaneously in rabbits but failed to produce actinomycosis.

I took a good deal of interest in examining the discharges from these lesions. There are observable among the pus cells irregularly shaped interlacements of very delicate filaments, containing in their interstices aggregations of minute bodies irregularly rectangular in shape. There were also present considerable numbers of the characteristic yellow bodies already mentioned as being visible to the naked eye. These latter seemed on examination to consist of a yellowish *amorphous* central core, an intermediate interlacement of filaments and a peripheral dressing of club-like bodies. It does not seem very difficult, I think, to imagine the filamentous interlacements blossoming out into full-blown characteristic bodies. This imagination was strengthened by observing sections of young colonies of aspergillus glaucus and noting the relationship between the *strongly* eosinophile and charmingly graceful fruit-heads and the basophile mycelium from which they spring.

Cheltenham.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF SCHÖNLEIN'S PURPURA.

BY EDWARD C. B. IBOTSON, M.B. LOND.

I WAS summoned in the evening of June 11th last *to* see a boy, aged two years, as something unusual had been noticed in the state of his penis. I found a tight and much swollen prepuce in the *condition of* phimosis. His mother attributed this to a fall. I also observed that there were some large purple spots on the left thigh. I punctured the œdematous prepuce, squeezed out some of the serum, and ordered lead lotion to be applied frequently. His temperature was normal. On the next day (June 12th) there was still some phimosis, so the lead lotion was continued. The boy's temperature was now 100° F. and there was a copious purpuric eruption on the legs and arms. The parents were naturally alarmed, fearing some malignant infectious fever. I was, however, able to reassure them, pointing out that there were no *signs of variola*, measles, or scarlet fever. I also said that in my opinion the disease was either purpura or scurvy and I ordered lime-juice well sweetened to be freely given. *On* the following day there was some urticaria and in the centre of some of the wheals there was purpura. The purpura was strictly confined to the extremities—namely, the legs, the thighs, the buttocks, the arms, and the forearms. Some of the patches measured one or two inches in diameter. On the 14th there were painful swelling of the *left knee-joint and tenderness* of all the bones; a purpuric eruption had also commenced on the face. The boy's temperature on the 13th and 14th was normal. I prescribed a mixture containing 24 minims of suprarenalin (Armour), 20 minims of liquor rosæ dulcis, and water to make up one and a half ounces; *one drachm to be taken every four hours.* I also ordered the knee to be wrapped in cotton-wool and bandaged. Those purpuric patches which had faded left a brown stain behind. On the 15th the swelling of the knee was better and the œdema of the prepuce was gone. There was no further eruption on the extremities but some fresh spots had come out on the face. The child was sitting up and appeared to be much better; his bones were also less tender. On the 16th all swelling in the knee was gone; the patient continued to take the suprarenalin. On the 20th nearly all the purpuroid patches on the face were gone, leaving brown stains, and the boy was much better.

The case illustrates the following points: (1) combination of wheals and purpura, a combination which is diagnostic if not pathognomonic; (2) moderate pyrexia at the commencement of the illness; (3) swelling of the knee and prepuce; and (4) rapid beneficial action of suprarenalin.

Dover.

A CASE OF CEREBRO-SPINAL MENINGITIS.

By *John M. Bennion*, M.B., B.C. Cantab.

IN THE LANCET of June 30th, p. 1815, I read with great interest an article by Dr. William Wright and Dr. William Archibald on Epidemic Cerebro-spinal Meningitis and it has induced me to send you the notes of the following case.

The patient, who was a girl, aged six years, was taken ill on June 23rd last with severe headache and the "cold shivers." On the 24th she vomited several times, the mother stating *that the child could keep nothing down.* On the 25th, when I saw her for the first time, she was unconscious and delirious, the pupils were large, there was a patch of herpes on the lower lip, and the head was retracted. The temperature was 101·2° F. and the pulse-rate was 80. The knee-jerks on both sides were exaggerated and Kernig's sign was present. Nothing abnormal was observed in the chest. *The girl was* much worse on the morning of the 26th, the temperature being 102·6° and the pulse-rate 120; the respirations were 48 per minute and were noisy owing to mucus in the throat. A squint was noted. The retraction of the head was more marked. There were constant convulsions which involved the face and all four limbs. It was obvious that the child could not live long and she died early on the morning of the 27th. No lumbar puncture was performed and unfortunately a post-mortem examination was not allowed.

At first sight I thought that the case was one of tuberculous meningitis but the sudden onset, the labial herpes, and the abrupt termination, I think, justify the diagnosis of cerebro spinal meningitis. Up to the present no other member of the family has been attacked.

St. Mary Cray, Kent.

A CASE OF ABSENCE OF THE UTERUS.

By Alice Maud Soradji, M.B., B.S. Lond.

THE patient, who was a Hindoo, aged 19 years, came to me complaining of never having menstruated. She was well-built and well-developed, in fact rather broader and stronger than *other* girls of her class and age. In appearance there was nothing abnormal about her face or body. She had no hair about the face except *the faintest trace on* her upper lip. The breasts were well developed. The labia majora were very small and tightly stretched from the anterior to the posterior end; there were no folds representing the labia minora; the clitoris was hypertrophied. On making a vaginal examination the vagina was found to be quite small, only one and a half inches deep at most. No uterus was found. In the posterior wall of the vagina the mucous membrane was at one spot slightly puckered round a central point. She was married. She *complained* of a "*fulness*" in the head and the lower part of the abdomen which recurred every four weeks.

ROYAL WATERLOO HOSPITAL FOR CHILDREN AND WOMEN.

A CASE OF APPENDIX ABSCESS WITH AN UNUSUAL COMPLICATION.

(Under the care of Mr. RUSSELL J. HOWARD.)

THE patient, a female, aged 17 years, was admitted to the Royal Waterloo Hospital on Feb. 7th, 1906, complaining of abdominal pain and vomiting. She gave the following history. Whilst dressing on the afternoon of Jan. 24th she was suddenly seized with pain in the right lower abdomen and vomited. She went to bed and was kept on milk and beef-tea but had no medical attendance. Four days after the onset, the symptoms being relieved, she was sent to her own home. There she was confined to bed for most of the day but got up in the afternoon and went to see her medical adviser who prescribed treatment. As the vomiting continued, on Feb. 7th she went to the hospital by omnibus and tram from Wimbledon. During her illness she had taken nothing but milk and beef-tea as she had vomited every day. During the first week the bowels had not been opened but after taking medicine the patient had had diarrhœa.

On admission she complained of pain in the right iliac fossa and a lump which her mother had discovered, nausea, and diarrhœa. She showed the abdominal facies; her tongue was coated and dry. The temperature was 100° F., the pulse was 116, and the respirations were 34. On abdominal examination there was an obvious swelling in the appendix area both to sight and touch. This swelling was *resonant on percussion* and was situated rather higher and more internally than the usual appendix abscess. Abdominal respiration was slight and there was marked muscular rigidity of the abdominal walls. Rectal examination made under an anæsthetic revealed nothing abnormal in the pelvis. The diagnosis made was retrocæcal appendix abscess.

Operation was *performed six hours after* admission. An incision was made over the most prominent part of the swelling and on opening the peritoneal cavity the cæcum came into view and there was an entire absence of adhesions in front. The general peritoneal cavity was shut off with gauze and a slight search revealed an abscess situated in the angle between the ileum and the cæcum, which contained about two ounces of foul-smelling pus. The cavity passed in an upward direction behind the ileum and the cæcum. The appendix *was not seen and no concretion was* found. The abscess cavity and the pouch of Douglas were drained with indiarubber tubes and the wound was partially united with sutures. After the operation the pulse was 115, the temperature was 101°, and the respirations were 35.

Progress.—On Feb. 8th the pulse was 112, the respirations were 37, and the temperature was 98°. Pus was passing out of the *abscess cavity* but none from Douglas's pouch. There was some abdominal pain but no distension. Incontinence of urine *and fæces was present.* On the 9th the pulse was 130, the respirations were 45, and the temperature was 99°. There was no general abdominal pain or distension but some vomiting was present. Offensive pus came from both tubes. On the 10th there were some abdominal distension and slight vomiting. The general condition had improved. The pulse was 120, the respirations were 25, and the temperature was 99·6°. On the 12th there were still abdominal distension and slight vomiting but food was taken well. The tongue was moist. The pulse was 130, the respirations were 35, and the temperature was 99°. A turpentine enema was administered which gave relief. At 10 P.M. on the 12th there was considerable hæmorrhage from the wound which soaked the dressing and filled both tubes with blood clot. When the wound was examined the bleeding had stopped; the tubes were removed, a gauze drain was substituted, and a light dressing was applied, the wound being disturbed as little as possible. The pulse was 158. No further hæmorrhage occurred from the wound but the patient died suddenly at 2 A.M. on the 13th.

Necropsy.—On opening the abdomen the small intestine was distended and pus was found spreading from the abscess region over the parietal peritoneum but there was no pus or lymph between the coils of the intestine. The large bowel was contracted and there was a large quantity of blood and pus in Douglas's pouch. The appendix was found lying behind the cæcum and running upwards and slightly inwards (Fig. 1); it was about four inches long and the last inch was completely gangrenous; there was no concretion. The abscess cavity was behind, and somewhat internal to, the cæcum and behind the last part of the ileum. The walls of the cavity were formed by the following structures—cæcum, ileum, duodenum (second part), psoas muscle, iliac vein, vena cava, and the iliac fascia in the right iliac fossa (Fig. 2). In the cavity were pus and blood clot. In the duodenum just where it turns up and in to run across the right crus of the diaphragm was a perforation with sloughing edges of about the size of a pea. The ulceration on the mucous surface was smaller than that on the peritoneal. On opening the duodenum and ileum they were found to contain a large quantity of blood. The iliac veins and the vena cava were normal. The rest of the organs were normal.

FIG. 1.

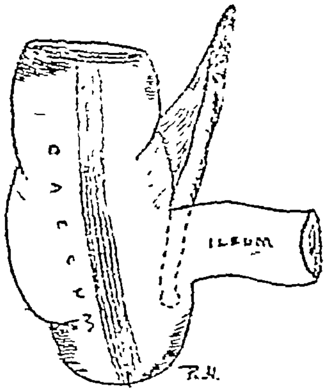

Diagram showing position of appendix.

FIG. 2.

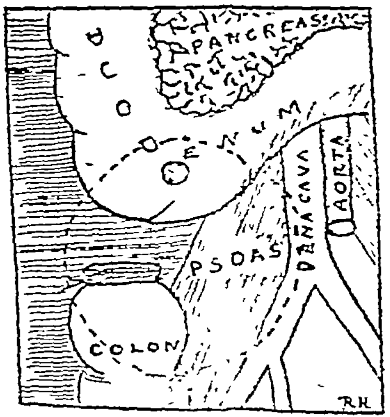

Diagram showing position of abscess cavity within dotted circle and perforation of duodenum.

Remarks by Mr. RUSSELL HOWARD.—The interest of this case lies in the two complications—hæmorrhage and perforation of the duodenum.

Hæmorrhage is a fairly well known complication and appears to be usually from erosion of the iliac vessels or the deep circumflex iliac artery. J. C. Lewis[1] records a case of hæmorrhage from the common iliac vein. G. Soudille[2] relates a fatal case with hæmorrhage from the external iliac artery. J. D. Malcolm[3] at the Clinical Society of London reported a case with severe hæmorrhage which recovered, the source of the bleeding not being ascertained, and in the discussion that followed other cases were mentioned, Charters Symonds reporting a case in which he found the external iliac artery and vein opened. Box and Wallace[4] report a fatal case of bleeding but the source of the hæmorrhage was not discovered; two severe hæmorrhages occurred per rectum. Ramsay[5] records a case of sloughing of the external iliac artery in which the vessel was ligatured and recovery took place. Dyce Duckworth reports a case in which the hæmorrhage occurred on the eighth day, with recovery. Moynihan, quoting Murphy and Mayo, states that the bleeding occurs from small vessels on the inner side of the appendix.

Perforation of the stomach and duodenum are also well-known complications and the following cases have been reported. Dieulafoy[6] records a fatal case of hæmatemesis following removal of the appendix in which acute necrosis of the mucous membrane of the stomach was found. Warren Low[7] reports a case of perforation of an ulcer of the stomach with appendicitis. Ledlard and Sedgwick[8] report a case of perforation of an ulcer on the pancreatic surface of the second part of the duodenum; there was no acute inflammation of the appendix and the abdomen was not drained. In the same paper they also quote a case of gastric ulcer under the care of F. Victor Milward. Watson Cheyne and H. Wilbe[9] report a case of perforated gastric ulcer with appendicitis. Bolton Carter[10] gives particulars of a case of an appendix abscess which was opened and drained with an indiarubber tube in which there was hæmorrhage from the wound and death occurred. Post mortem the appendix was gangrenous and lying deeply over the pelvic brim. The ulcer which had perforated was on the anterior surface of the second part of the duodenum. The direction in which the abscess had tracked and the direction in which the tube was inserted are not given.

The case described differs from all those quoted above in that the perforation in the duodenum was in the wall of the abscess and that the perforation was certainly *into* the duodenum. Whether the perforation was caused by the tube used for drainage resting against the duodenum is doubtful, as it was removed and gauze was substituted when the hæmorrhage occurred, but from the direction in which the tube ran it most likely did rest against the second part of the duodenum and was the cause of the fatal result. The case described by Bolton Carter may have been of this nature but in his case the appendix was hanging over the brim of the pelvis and the abscess wall probably did not include the duodenum.

KIDDERMINSTER INFIRMARY AND CHILDREN'S HOSPITAL.

A CASE OF SUCCESSFUL EXCISION OF A PORTION OF THE RIGHT LUNG FOR PULMONARY TUBERCULOSIS.

(Under the care of Mr. J. LIONEL STRETTON.)

THE patient, a female, aged 28 years, was admitted to the infirmary on July 19th, 1900. There were signs of tuberculous disease at the apex of the right lung, for which she was treated with increasing doses of creasote with temporary benefit. After her discharge the symptoms—cough, expectoration, and night sweats—increased in severity and she suggested the possibility of removing the diseased portion of lung. A full explanation of the danger was given to her and to her husband and they both desired the operation to be undertaken. She was readmitted on August 2nd, 1900, when the following note was made. "The patient gives a history of being treated four years ago for a delicate chest. For the past year and a half she has had a continuous cough with expectoration and night sweats; she has also been losing flesh. There is dulness over the right apex as far down as the lower border of the third rib. Tubular breathing and crepitant râles. The evening temperature is slightly raised and she has night sweats. The urine contains a trace of albumin."

On August 7th the patient was placed under ether. A vertical incision was made, about three inches long, with its centre over the third rib, two inches from, and parallel to, the breast bone. The third rib was separated from its cartilage and about four inches of it removed. On opening the pleura the lung was found closely adherent. The hand was introduced and the adhesions were with great difficulty separated down to the lower level of the third rib. There was profuse hæmorrhage, which was arrested by sponge pressure. The portion of lung separated was then surrounded with a serre-nœud and cut away, leaving a stump of about the size of a five-shilling piece.

[9] THE LANCET, June 11th, 1904, p. 1641.
[10] THE LANCET, Nov. 2nd, 1901, p. 1194.

For the first 24 hours after the operation the patient remained in a very collapsed condition and suffered from pain and cough. At the end of 48 hours an attempt was made to remove the serre-nœud, but as rather free hæmorrhage occurred the wire was twisted and left on. For the next few days there were considerable difficulty in breathing, constant cough, and hæmorrhagic expectoration. There was also a good deal of hæmorrhage from the wound. Blood was found to collect in the pleura and had to be removed with a syringe. The breathing and cough gradually improved and the hæmorrhage ceased after the seventh day. In spite of great care with the dressings symptoms of sepsis supervened and on the 22nd it was deemed advisable to make a counter opening in the back and thread a large drainage-tube through. From that date improvement was continuous though slow. The wire came away on the 25th. The tube was removed on Nov. 7th and the wound was healed by the 14th. Her cough and expectoration entirely ceased by Nov. 23rd.

A specimen of the sputum was sent to the Worcestershire county council laboratory for examination at the end of October and the report stated that no bacilli could be found. The portion of lung removed consisted of about half of the right upper lobe and contained a cavity. Unfortunately it was destroyed before a thorough examination had been made.

Remarks by MR. STRETTON.—As I was unable to find any account of a similar operation it was necessary to devise the method of performing it. The chief difficulty I foresaw was the question of adhesions and this proved to be correct. The removal of one rib gave ample room for all the manipulations. It was found impossible to fix the stump in the wound because this caused dragging on the root of the lung accompanied by alarming symptoms of collapse. In future this difficulty could be overcome by removing several ribs and so allowing the chest wall to be brought down to the stump.

I had a letter from the patient in June of this year. She is still travelling about as a hawker but as she has not been in this town since I am unable to state what condition her lung is in.

The removal of a portion of lung for the cure of pulmonary tuberculosis is no doubt heroic and it is probable that it will be some time before patients will submit to the risk involved. With increased experience I have no doubt that the danger can be considerably lessened. The operation is not one of extreme difficulty and if cases were secured at an early stage the percentage of recoveries would probably be greater than are obtained under the methods of treatment now adopted.

Medical Societies.

OBSTETRICAL SOCIETY OF LONDON.

Primary Cancer of the Ovary.—Contracted Pelvis.—Adenoma of the Labium.—Exhibition of Specimens.

A MEETING of this society was held on July 4th, Dr. W. R. DAKIN, the President, being in the chair.

Dr. A. LOUISE MCILROY read a paper (followed by a demonstration) on Primary Cancer of the Ovary. Primary cancer of the ovary occurred in women about the time of the menopause or after, but was found in young patients; in the latter cases menstruation was influenced, cessation of the periods occurring. Previous child-bearing had no influence. Pain was not a marked symptom, patients seeking operation on account of the swelling of the abdomen. Ascites was present in most cases. Metastasis depended upon the duration of the disease and the integrity of the tumour capsule. The probability of recurrence was great. Malignancy was rarely suspected previously to the operation. Both ovaries were frequently affected, one showing a more advanced stage of the disease than the other. In the early stage the capsule was firm but later it became broken down and tumour tissue proliferated through it. Germinal epithelium was absent as a rule. No Graafian follicles or corpora lutea were found. Previous benign change in the ovary was always present. The most common forms of cancer in the ovary were the glandular cystic form and the alveolar with connective tissue increase. The growth was found near the surface and in the folds in early specimens. The origin of the growth was from the follicle cells and from cells which had been derived from the germinal epithelium. The so-called ova of the German pathologists were masses of degenerated protoplasm; they were retrogressive products of the follicle cells. Karyokinesis was not well marked in these cancer-cell tumours. The cells found in cancer of the ovary resembled those found in benign growths, but differed in their distribution, irregular arrangement, and in the amount of proliferation.—Dr. T. W. EDEN said that on two points, at any rate, Dr. McIlroy appeared to have made an important contribution to their knowledge. One point was that she had traced the invasion of the ovarian stroma by cells derived from malignant changes in the germinal epithelium. The second was that she believed she had traced the transition stages by which the epithelial cells of a benign cyst became transformed into the malignant cells of an adeno-carcinoma.—Dr. H. RUSSELL ANDREWS congratulated Dr. McIlroy on the excellent demonstration that she had given and asked her whether her researches had led her to agree with the teaching of some German writers that many adenomatous or pseudo-mucinous ovarian cysts which appeared to be perfectly innocent to the naked eye proved to be malignant on microscopical examination. If this teaching were accepted it became the surgeon's duty to remove all adenomatous ovarian tumours whole without diminishing their size by tapping, however large they might be.—Mr. J. S. FAIRBAIRN said that there was one point in the paper which he had not been able to follow and that was the statement that the carcinomatous tumours in all cases followed on a previously benign growth. The proof of this was far from complete and, as he understood, was based on observation of histological changes in different parts of the tumour, in other words, on tracing the transition of a regular goblet-celled epithelium into an irregular epithelium growth of carcinomatous cell.—Dr. H. WILLIAMSON said that from his own observations he could confirm two of the conclusions which Dr. McIlroy had arrived at. The first was with regard to the development of the cells of the membrana granulosa and the second was the recognition of the part played by later downgrowths of the germinal epithelium in the genesis of ovarian tumours.—Dr. MARY THORNE did not consider that pain was such a very rare symptom in the earliest stage of carcinoma of the ovary and quoted a case of her own in which acute pain was the first thing which attracted attention.—Dr. MCILROY replied.

A short communication was read by Dr. O. J. NEPEAN LONGRIDGE on 64 Cases of Contracted Pelvis. These cases were treated during 1905 at Queen Charlotte's Hospital. The system of admission was arranged so that it was possible to recognise and treat if necessary the cases of contracted pelvis at an early date. The results in these cases were satisfactory as regarded the mothers, no death or serious complication being noted. Eight infants died, three of whom were suffering from some abnormality incompatible with life. A special feature of this series was a group of 14 cases in which labour was unaided and spontaneous, the most remarkable case being a primipara who gave birth to a living child weighing 5 pounds and 12¾ ounces through a true conjugate of two and seven-eighths inches in ten hours. Nine of these patients were primiparæ and five were multiparæ. Two of the infants were born dead, one being macerated and one hydrocephalic. Labour was induced by bougies in 17 multiparæ and in six primiparæ. The date of induction was determined by estimating the relative size of the head and the pelvis. Delivery was unaided in 17 cases, five patients were delivered by forceps, and one by version. The mothers all made a good recovery and one infant was born dead. A second infant died on the third day with an imperforate anus. The time which elapsed between the passage of the bougies and the birth of the child averaged 92·6 hours. In 18 of the 64 cases delivery was brought about by forceps and in five after induction; the mothers and infants did well with the exception that in one case the cord was prolapsed and the infant died. The occiput was posterior in 14 cases and was rotated forwards by the hand in six. Version was performed in six cases in which contraction was present. Two infants died and the mothers did well Cæsarean section was performed in nine cases. The mothers all did well and one infant died. In one case the operation was performed for the second time. The treatment of contracted pelvis appeared to be narrowing down to two methods of election—namely, induction and Cæsarean section, and the experience gained at Queen Charlotte's Hospital tended to show that the former was a satisfactory procedure with a conjugate of three and a half inches and over, whereas Cæsarean section was the best method to adopt in cases with conjugates of about three inches and under.—Dr. W Rivers Pollock thought that Dr. Longridge in his excellent paper had spoken too disparagingly of de Ribes's bag. If the bougie failed for three days to bring on labour it could be safely and rapidly induced by the introduction of the bag followed by traction. When the bag was expelled the os uteri was fully dilated and rapid delivery could be safely effected. The uterus would be found to retract and contract well after the expulsion of the placenta.—Mr. J. H. Targett congratulated Dr. Longridge on his interesting and valuable clinical report of the work done at Queen Charlotte's Hospital during 1905. With regard to the use of de Ribes's bag he found it a valuable means of inducing uterine action when bougies had failed to excite premature labour. He thought that it was best to introduce the bag in Sims's position and to place it between the membranes and the uterine wall. By so doing compression of the umbilical cord was prevented and the prematurely born child did not suffer from direct uterine pressure as after the escape of the liquor amnii.—Dr. Longridge replied.

Dr. Williamson read a short communication on Adenoma of the Labium. The patient from whom the specimen was removed was an unmarried woman, aged 62 years, who for two and a half years had suffered from a slight blood-stained vaginal discharge and on one occasion, a year before she came under observation, from a somewhat profuse hæmorrhage. On the right labium majus was a small growth equal in size to a split pea; it was soft, of a pinkish colour, and bled readily on touch. The growth was diagnosed as an epithelioma and was removed by Dr. F. H. Champneys in 1903. No recurrence had taken place. On microscopical examination the tumour proved to be an adenoma composed of irregular branching tubes lined by columnar epithelium; some parts of the growth were so irregular as to suggest carcinoma. Three similar cases had been reported, two by Pick and one by Schickele, and brief accounts of those cases were given. Dr. Williamson then discussed the pathology of the condition, reviewing the theories of Schickele and Pick; the former regarded the growths as arising in abnormal "rests" of the Wolffian body and duct, the latter believed them to be adenomata arising in connexion with the sweat glands. Dr. Williamson regarded the latter theory of origin as the more probable. Attention was directed to the close resemblance which the growths bear to certain forms of malignant adenoma and he concluded by stating that as this case had been under observation longer than any of those previously recorded he offered it as a contribution to the natural history of the growths —Dr. Herbert R. Spencer did not think that these growths were as rare as appeared in the paper. He had met with two cases himself and thought that Dr. Williamson had overlooked some cases in the literature. The origin of these growths was by no means certain. Mr. Lawrence, the curator of the museum at University College, was of opinion that they probably arose in sebaceous glands on the grounds that they had a distinctly lobulated structure and the tubules had such a distinct racemose arrangement as to leave no doubt that they did not arise from tubular glands. —Dr. Williamson in reply, said he thought that the tumours referred to by Dr. Spencer were sebaceous adenomata and belonged to a class different from those now under discussion.

The following specimens were shown:—

Dr. Spencer: Specimen from a case of Cæsarean Section followed by Hysterectomy for Fibroids complicating Labour.

Dr. Andrews: (1) A Degenerating Fibroid removed during the Puerperium; and (2) A large Cystic Fibroid.

OPHTHALMOLOGICAL SOCIETY.

Congenital Distichiasis.—The Structure of the Choroid at the Macula.—Unilateral White Eyelashes and Tufts of Hair.

A meeting of this society was held on July 13th, Mr. J. Priestley Smith, the President, being in the chair.

Mr. A. R. Brailey read a paper on Congenital Distichiasis and gave a clinical description of a case together with the result obtained by making a microscopic examination of a small portion of the lids. The chief point of interest was the fact that the Meibomian glands were apparently completely absent and their place was taken by hair follicles. He then gave a description of four other cases seen in the clinic of Professor Fuchs at Vienna. These were the only cases seen there during a period of 20 years and show how extremely rare this deformity is. He also described a case reported by Kuhnt. Mr. Brailey drew attention to the distinction which should be recognised between trichiasis and distichiasis and urged the advisability of limiting the latter term to the congenital cases. He gave a list of other cases which had been reported.

Mr. C. H. Usher read a note on the Choroid at the Macular Region. He drew attention to the fact that in sections of albinos' eyes examined by Mr. E. Nettleship and shown at the meeting of the society in November last pigment was present in the choroid but limited to the spot corresponding to the yellow spot region. He had since examined 11 normally pigmented eyes and had found: (1) a deeper pigmentation of the retinal epithelium at the yellow spot region and an increased thickness of this layer; (2) a marked increase in the pigmentation of the choroid; and (3) an increase in the thickness of the choroid. From the above observations it might be expected that if pigment was present at all in an albino's eye it would be found in the macular region.

Mr. Usher also read a paper on a case of Unilateral White Eyelashes and Tufts of Hair. The patient was a girl, aged three years, whose eyelashes on the left side were quite white and she also had two tufts of white hair on the left side of her head. There was nothing else abnormal in the mother or child and the pregnancy was normal in every way. The condition was first noticed about the third day after birth. All the eyelashes on the right side were light brown in colour, so also was the greater part of the hair of the head. The family history was carefully drawn out and although there were some albinos in the family yet no other member seems to have had this peculiar condition.

Dermatological Society of London.—A meeting of this society was held on July 11th, Dr. H. Radcliffe Crocker being in the chair.—Dr. James Galloway showed a case for diagnosis of a Seasonal Eruption on the Face of a middle-aged woman. Dr. Galloway had thought that the condition was possibly a form of lupus erythematosus, but there had been vesication and he was inclined to consider it as allied to hydroa æstivale. This opinion was supported by the majority of those present.—Dr. Crocker showed a case of Mycosis Fungoides of very typical character in an old man who had been treated with the x rays with considerable benefit before going to Dr. Crocker. The disease was now present on the legs, the forehead, and the face, the skin in these parts being much infiltrated and the patient suffering from great irritation. The treatment with the x rays was being continued.—Dr. T. Colcott Fox showed a case for diagnosis—a very extensive Pink and Scaly Eruption occupying the greater part of the trunk, the arms, forearms, and hands; there had also been vesicles on the fingers and toes. Dr. Fox suggested the diagnosis of pityriasis rosea which found many supporters.—Dr. Crocker and Sir E. Cooper Perry thought that it was more probably a case of seborrhœic eczema.—Mr. Malcolm Morris showed a father and daughter, the subjects of Congenital Tylosis. In both patients the skin of the palms and the soles had been immensely thickened and hardened from birth, the keratodermic areas being bounded by an erythematous border. There were two other children in the family who remained wholly free from the disease.—Mr. George Pernet showed a young man whom he had treated for Linear Nævus of the Hand and Forearm with scraping and the application of carbolic acid. Some members considered the case as more typical of tuberculosis verrucosa cutis.—Dr. J. M. H. Macleod showed a case of Multiple Idiopathic

Keloid in a man, aged 65 years. He had a large patch of keloid on the chest and several smaller patches of similar character upon the shoulders and back. All the patches were violently itchy. No history of any previous injury to account for the development of the keloids could be obtained.—Dr. Wilfrid S. Fox showed a typical case of Adenoma Sebaceum in a little boy, the subject of epileptic fits. The disease had been noted for the first time at the age of three years after the child had had several fits.—Dr. E. G. Graham Little showed: 1. A girl, aged five years, who had had an extensive eruption of Sclerodermia upon the scalp, the face, and the body for the past 18 months. There was also marked hemiatrophy of the face on the affected side and of the tongue. All the lesions were on the left side of the body. The child appeared to be delicate and had a quantity of downy hair covering the midvertebral line. 2. A case of Rodent Ulcer in an elderly man who had had this ulcer for 25 years and who had been treated for it with some success with the x rays. In the past fortnight he had developed upon the site of the unhealed rodent ulcer a tumour of the size of a Barcelona nut. The general opinion was that this fresh development was epitheliomatous and in view of the extreme rapidity of its growth immediate excision was recommended.

Reviews and Notices of Books.

A Handbook of Climatic Treatment, including Balneology. By WILLIAM R. HUGGARD, M.A., M.D. R.U.I., F.R.C.P. Lond., H.B.M. Consul at Davos, Switzerland. London: Macmillan and Co. 1906. Pp. xvi.-536. Price 12*s.* 6*d.* net.

Dr. Huggard in the valuable book before us has produced a volume which should serve as a most useful work of reference for any practitioner who has frequently to recommend climatic or balneological treatment for his patients. We are told in the preface that the chief aims of the book are to place the therapeutics of climate on a sure foundation and to enable the physician readily to master the principles of choice in the selection of baths and mineral waters. We may congratulate Dr. Huggard upon the success which has attended his treatment of his subjects, for the result has been to produce a volume which is a mine of useful information, written in a manner most convenient for reference and in interesting style. The critical character of his consideration of the uses and actions of climate and the rigid analysis to which he subjects the claims of various health resorts, watering places, and baths from the standpoint of physiological experiments, as well as that of experience, greatly enhance the value of the work. We find no mere copy of the self-advertised virtues of the various resorts and their mineral waters but simply the indications which should suggest their recommendation and the benefits which may be expected from them, while their limitations and contra-indications are carefully set forth.

In analysing the action of climate and its influence upon bodily health and functions a section is devoted to a concise presentation of the principal factors of meteorology, with especial reference to their medical bearing. The atmosphere, temperature, humidity, barometric pressure, and atmospheric electricity are all considered in detail, and the influence which each factor exerts upon climate is carefully and exhaustively set forth. This section concludes with a chapter devoted to general influences affecting climate, including those of land, water, wind, forests, and mountains.

The second section deals with the physiology of climate; in it the various meteorological factors are considered from the standpoint of their actions upon the organism in health and disease. This part of the work contains a wealth of most interesting information upon the reaction of the organism to changes in its surroundings, each meteorological factor being considered separately in regard to its effects upon the body generally and upon the various organs and their functions. This section contains exhaustive references to the various experimental observations which have been made on the subject and forms a most comprehensive and scientific basis from which to study the practical applications of climatic treatment. The general principle which Dr. Huggard deduces is that "the most fundamental point in the action of climate is its influence on tissue change." The demand for tissue change depends "on the surrounding temperature, as well as on the wind, moisture and all other circumstances affecting the abstraction of heat." The importance, however, of the patient's power of response is very strongly emphasised; it is found that individuals react very differently to the same external conditions, and in recommending a certain climate it is necessary to gauge beforehand how the particular individual will respond to the greater or less demand for heat induced by it. It is obvious that this determination of the patient's powers of response is of great importance, and Dr. Huggard states that careful inquiry of the patient as to how he bears heat and cold, combined with a careful study of the bodily functions, will enable a right conclusion to be made in the great majority of cases in accordance with his general principle that "the best climate for a person is that where nutrition is at the highest level, and nutrition is at the highest level where the demand for tissue change—the demand for the production of heat—best coincides with the patient's power of response." An interesting discussion of the question of acclimatisation is also given in this section.

The third part of the book deals with climates and health resorts and commences with a classification of climates upon the basis of the demand made by each climate for the production of heat. The various health resorts of the world are then described, with especial reference to the climatic conditions obtaining at each and their value in different conditions of disease or ill-health. An interesting chapter on the Ocean as a Health Resort is included in this section.

Part IV. is devoted to the consideration of baths and mineral waters. The therapeutics of the different forms of baths and of the external application of the various mineral waters are critically considered and in like manner the actions of the various waters when taken internally are carefully set forth and compared with the known pharmacological actions of their principal constituents. The various waters are classified into two main groups—depurative and tonic. The former comprises the abluent, stomachic and diuretic, and the aperient waters, the latter the hæmatogenic, and the alterative and nervine. The examples of the different groups are given with analyses of their various springs and the conditions for which they are recommended. Throughout this section Dr. Huggard is most cautious in his recommendations. At the commencement he refers to the air of mystery which has always hung around mineral waters and points out that "owing to vague tradition and to the parade in analyses of strange and unimportant constituents mineral waters are still more or less cloaked in mystery," and further points out the special qualities which custom and tradition may have assigned to different waters of essentially the same therapeutic value, instancing the purely arbitrary distinctions which therefore have to be borne in mind in order to avoid "sending to Saint-Sauveur, which is essentially a ladies' bath, a case suitable for Aix-la-Chapelle, which is chiefly given over to the treatment of syphilis in men." As a temperate and practical exposition of the uses of baths and mineral waters this section of the work leaves nothing to be desired.

The concluding part deals with the therapeutics of climate and mineral waters under the headings of various diseases. Their application in cases of obesity, of metabolic disturbances, of heart disease, and various local diseases is

Reviews

described. Under the heading of Tuberculosis are given the principles upon which depends the selection of a climate or of a sanatorium for different classes of cases.

Dr. Huggard's book represents the outcome of very considerable labour; it contains a large amount of useful and practical information in convenient form which it would be difficult to obtain elsewhere. The method he has adopted necessarily entails considerable repetition but this is an advantage from the point of view of facility of reference and, moreover, he is always clear in his statements and practical in his recommendations.

Pathogenic Micro-organisms, including Bacteria and Protozoa: a Practical Manual for Students, Physicians, and Health Officers. By WILLIAM HALLOCK PARK, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Research Laboratory of the Department of Health, City of New York. Assisted by ANNA W. WILLIAMS, M.D., Assistant Director of the Research Laboratory. Second edition, enlarged and thoroughly revised. With 165 engravings and four full-page plates. London: Henry Kimpton. 1906. Pp. 556. Price 18*s.* net.

THIS work possesses a distinct character and individuality which make the appearance of a second edition very welcome. Amongst the large number of text-books of bacteriology by American authors it is a relief to find one in which the introduction of purely scientific matter appears to be considered as well worth some slight loss of the hard practical efficiency which seems to be the ideal of most of those excellent works. There are, as might be expected, many evidences in the book of the connexion of the author with the Department of Health of New York and the incorporation of much original work done in the research laboratory of that department makes it differ from other text-books and gives it a peculiar value for the practitioner and health officer. As a consequence of this introduction of original work there appears to be an inequality in the treatment of the various subjects but the inequality is due rather to the fact that certain sections rise considerably above, rather than that the less conspicuous sections fall below, the level found in the average text-book.

An important feature of the present edition is the large section devoted to the protozoa the importance of which in the production of disease is now so fully recognised. The bacteriological section has been very thoroughly revised and brought quite up to date. The general plan of the book is that found in most text-books on the subject and of the early part of the work on the classification, cultivation, and general biology of micro-organisms little need be said except to point out that the chapters on practical disinfection and sterilisation are good and that in the consideration of the substances concerned in agglutination the results of much valuable work on the relations of the "group" to "specific" agglutinins are embodied. These results seem likely to be of much importance in differentiating and grouping members of that large and puzzling class of organisms to which belong the typhoid, dysentery, and colon bacilli.

Part II. deals with the pathogenic bacteria and opens with a chapter on Diphtheria which is full of information derived from personal observation and the work of investigators in the research laboratory. The best account of the pseudo-diphtheria bacilli and their relation to the virulent bacillus which we know is to be found here, and after full discussion the practical conclusion is reached that, "in this region (New York) at least, non-virulent diphtheria-like organisms retain their characteristics under various artificial and natural conditions and that they may be regarded from the public health standpoint as harmless." The author does not appear to accept Ehrlich's theories on the constitution of diphtheria toxin as proved.

The chapters on Tetanus and the Colon and Typhoid Bacilli are also important, and the statements made as to the relationships existing amongst the members of these latter groups, as determined by the agglutination test with sera from which the group agglutinins have been removed, are of interest. According to Dr. Park the members of the colon group do not constitute a distinct species as is the case with the typhoid bacilli, and the intermediate group is similarly divisible into a paratyphoid group—a distinct species—and a paracolon group containing several distinct species of culturally similar bacilli. In America the dysentery bacilli have attracted much attention and the more complete study of this group has led to the discovery of races which go far to bridge over the gap between the bacillus of Shiga and the colon bacillus. These intermediate organisms are grouped together as paradysentery bacilli. A long section is devoted to the bacillus tuberculosis. Very full directions are given for testing animals with tuberculin and for examining sputum for organisms associated with the tubercle bacillus with a view to prognosis; an estimate of the value of the results obtained is given. With regard to the vexed question of human and bovine tubercle, it is held that these bacilli represent very distinct races, so different, in fact, that it is possible to state that intestinal and mesenteric tubercle in children is largely due to bovine infection. The bacteriological examination of water occupies a short chapter, while a longer one deals with the bacteriology of milk in relation to disease, and much useful information acquired by the Health Department on the relations between the micro-organisms of milk and the summer diarrhœa of children is given.

The third part of the book, devoted to the diseases caused by protozoa, is written by Dr. Anna Williams, except the chapter on Malaria which is contributed by Mr. L. B. Goldhorn. This observer considers that it is possible from the morphology of the parasite to distinguish between recent infection and a relapse.

The book is well printed and the illustrations are well reproduced. In some cases the original photographs do not seem to be quite up to the standard of modern work. Dr. Park's book, since it does not simply add to the stock of text-books but contains much special information, may be strongly recommended to the serious student of bacteriology and public health.

A Practical Guide to the Administration of the "Nauheim" Treatment of Chronic Diseases of the Heart in England. By LESLIE O. THORNE THORNE, M.D., B.S. Durh. Second edition. London: Baillière, Tindall, and Cox. 1906. Pp. 75. Price 3*s.* 6*d.*

THIS little volume contains a good and full description of the details necessary in carrying out the mechanical treatment of chronic diseases of the heart. Dr. Thorne maintains that the "Nauheim" treatment can be efficiently administered in England, and in this book he gives minute directions as to how the baths are to be prepared and the manner in which the exercises are performed. In this edition he gives a good description of Schott's exercises and also illustrates the letterpress by means of 78 photographs, thereby considerably aiding those practitioners who have not actually seen the exercises demonstrated to understand more easily the necessary movements of the arms, the legs, and the trunk. These exercises are perfectly easy to learn but require some care in ascertaining whether the right amount of resistance is being exerted by the attendant, or, more important still, whether the movements are being made too rapidly. We are willing to grant that if these exercises are performed regularly and under skilled supervision the effect produced is quite as satisfactory as when they are carried out at Nauheim. As to the baths, we are not entirely convinced. It would be interesting to have an investigation conducted as to the comparative effect of the baths carried out with 20 to 40 gallons of water heated to 97° or 98° F. on the one hand and with water containing from four to five pounds of Droitwich salt and from five to six ounces of calcium chloride heated to the same temperature on the other hand—that is to say, to ascertain whether the salutary effects are due to the temperature of the water or to the contained salts. The "carbonated effervescent bath" would then be similarly tried. Such comparative trials may have been made already but we are not aware of them. We have, however, seen several forms of artificial "Nauheim" baths and were not favourably impressed with them.

Dr. Thorne, however, has evidently taken much trouble in the preparation of the book and some benefit will probably be obtained by following out his directions in suitable cases, for the number of patients who might receive benefit by a visit to Nauheim and are unable, for various reasons, to go there must be very large. Systematic exercise is doubtless a valuable therapeutic measure in certain cases of chronic diseases of the heart and Dr. Thorne indicates the nature of such cases. We thoroughly agree with him when he says: "The selection of suitable cases for treatment by the Nauheim methods is of vital importance, as there is no doubt that to treat thus every sufferer from chronic heart disease, irrespective of degree or kind, is most unwise." To apply the same therapeutic measures to every case of heart disease can only result in bringing into disrepute a valuable method of treatment.

A Handbook of Medical Jurisprudence and Toxicology for the use of Students and Practitioners. By WILLIAM A. BREND, M.A. Cantab., M.B., B.Sc. Lond., of the Inner Temple, Barrister at-Law. London: Charles Griffin and Co., Limited. 1906. Pp. 287.

THIS manual is intended primarily for the use of students and its scope should be sufficient for the ordinary pass examinations. Each branch of the subject has been dealt with in sufficient detail to enable the student to obtain a fair knowledge of forensic medicine. All the facts are clearly expressed but the letterpress is not over-burdened with illustrative examples or reports of trials. The whole work, however, is written in an interesting manner and should well serve the purpose for which it is intended.

The book should also be of value to the practitioner. To further that object Dr. Brend has made a successful endeavour to deal practically with those matters calling for the exercise of medico-legal skill and knowledge which are most likely to be met with in everyday clinical experience. To prepare evidence properly and to stand the test of cross-examination in criminal or civil cases may prove no easy matter, but in this handbook numerous hints are offered which will greatly assist the medical witness. Chapter XVII., entitled "The Obligations, Statutory and Moral, of the Medical Man," is of especial interest. A practitioner has many duties besides those of tending and healing the sick. Some of these—such as notification of infectious disease or certification of death—are imposed upon him by statute under pains and penalties for the non-performance thereof; others—as, for instance, the obtaining of a dying declaration from a wounded person or the assistance necessary to prepare a will in an emergency—have only a moral sanction for their performance. Circumstances of this nature are constantly occurring in ordinary practice and the precise methods of dealing with all such eventualities require to be known thoroughly. In the chapter now under consideration these points are dealt with *seriatim.* The directions and comments are brief and concise and we believe are perfectly trustworthy. The remarks on "When to refuse to certify or to inform the coroner of a death" are especially worthy of attention.

Another matter of considerable interest which naturally receives notice is that of malpraxis—that is to say, failure to exercise "reasonable skill and care in the treatment of a patient." A medical man is not, of course, expected to be infallible and cannot be held responsible for *bonâ fide* mistakes in either diagnosis or treatment, provided the errors are such that any prudent practitioner might in the circumstances have made and that no negligence has been displayed. Some cases are quoted which show the class of action likely to be brought against a medical practitioner for actual or supposed malpraxis. The various medical defence societies are doing most valuable work in protecting their members against such actions.

The question of professional secrecy receives due attention, as does also the subject of "undue influence."

We have perused the book with interest and can recommend it as a trustworthy work on medical jurisprudence and toxicology and one especially suitable for students and practitioners of medicine. Many of the works on forensic medicine are written with a view to being useful to members both of the medical and the legal professions, thereby rendering the books themselves bulky and any desired piece of information perhaps somewhat inaccessible on account of the large number of cases which are quoted, often in considerable detail. In this handbook, however, the necessary facts only are stated and consequently its contents will be more acceptable to those for whom it is intended.

Annual Report of the Veterinary Department of the Board of Agriculture and Fisheries for the Year 1905. Printed by Darling and Son, Bacon-street, E. 1906. Price 1*s.*

THE report is, as usual, divided into two parts: the report of the chief veterinary officer and that of the assistant secretary of the animals' division. From the combined reports we gather that at length swine fever has very materially decreased and that the number of outbreaks reported is considerably less than that of any preceding year. Thus, whilst in 1885 70 counties were affected and 7926 outbreaks were reported, with a total of 38,798 pigs attacked, in 1905 we find only 87 outbreaks reported and 3876 swine slaughtered as diseased or as having been exposed to infection. The decrease in the number of outbreaks of swine fever in Great Britain since the year 1901 has been continuous and the improvement has been shown in all parts of the country. It is also noticeable that in counties where the disease is still present the outbreaks are confined to much more circumscribed areas. By the application of the Swine Fever Order of 1903 to a county or group of counties, together with the suspension of the existing local regulations, the free movement of swine can be permitted throughout the entire area, whilst general restrictions can at once be imposed where such a course is necessary for the prevention of the spread of the disease. Sheep scab has also been successfully dealt with and shows a very material decrease. In England only 422 outbreaks were reported, as compared with 644 in the previous year; in Wales, 406, as compared with 708 in 1904; and in Scotland, 90, as compared with 66, making a total decrease for the whole of Great Britain of no fewer than 500 outbreaks. This is attributable largely to the increase in the practice of dipping.

In regard to glanders, the returns for the year show that there were 315 less outbreaks than in 1904, 590 fewer horses being returned as attacked by the disease. Apparently it is only now the question of obtaining money from the Treasury funds which is keeping the Board from adopting stern measures by which it is hoped to eradicate this fatal disease of horses and man. It is purely a question of fair and reasonable compensation to be granted to owners for all horses slaughtered as being in-contact animals and *only proved to be diseased by the mallein test*. It has not at present been found possible to obtain the necessary funds and it is to be hoped that it will not be long before the Government will see its way to grant these. Epizootic lymphangitis has been effectually checked and it is gratifying to read that only 19 cases have been met with outside the animals of the Army Veterinary Department. Anthrax shows only 907 outbreaks as compared with 1049 in 1904, but it is pointed out that the total number still exceeds considerably the total of any year since 1897 and, as stated by the assistant secretary to the Department, the control of this disease cannot yet be regarded as placed on a satisfactory basis. Parasitic mange and swine erysipelas each receive individual mention and it is with the greatest gratification that we note the entire absence of the heading of the word "rabies," this disease now being legitimately considered as extinct in Great Britain.

In conclusion, it may be said that the work of the Veterinary Department of the Board of Agriculture and Fisheries has been beneficial, both from the professional and the administrative aspects, to the stock owners and to the public at large.

Handbuch der Geburtshülfe. (Handbook of Midwifery.) In three volumes. Edited by F. VON WINCKEL. Vol. II., Part I., pp. x.–653; Part II., pp. xii–798. Glasgow: F. Bauermeister. Wiesbaden: J. F. Bergmann. Price 14*s.* 9*d.* and 18*s.* 8*d.* respectively.

THE appearance of the second volume of this important work will be welcomed by all who are interested in this branch of medicine. The complete work is destined long to remain a classic so far as the practice of German obstetricians is concerned.

The first half of the second volume opens with an article from the pen of the editor continuing his previous review of the history of gynæcology from the sixteenth to the eighteenth centuries and including a part of the nineteenth century. The succeeding articles are concerned with the physiology and dietetics of the puerperium and of the newly born infant. In his article on the puerperium Knapp discusses its physiology, the changes taking place during the process of involution of the genital organs, the care of the patient during the lying-in period, the diagnosis of this state, and its relations to medico-legal medicine. The important physiological processes which occur in the organs of the newly born infant in the period immediately following birth and the many important questions concerned with the study of metabolism at this period of life are discussed in detail by Seitz. The fourth section of the whole work is taken up with the Pathology of Pregnancy and its Treatment. This part of the book includes sections by Schaeffer on the Disturbances of Nutrition during Pregnancy, by R. von Braun-Fernwald on Prolapse of the Pregnant Uterus, by von Winckel on Hernia of the Gravid Uterus, and sections by Wertheim on Pregnancy complicated by mal-developments and anomalies in the position of the pelvic organs, myomata, carcinomata, diseases of the appendages, new growths, and extra-uterine gestation. Diseases affecting other parts than the genital organs are described by Freund, Meyer-Rügg, and von Winckel himself. We are surprised to find no mention of diseases of the heart in the last section; possibly this may be considered in a subsequent volume. The plan of dividing up these various subjects amongst a number of writers leads not infrequently to some repetition and greatly increases the length of the work. This can hardly be avoided and even if it could one of the most important features of a work of this kind is the opportunity which it affords of ascertaining the views of different authorities on the same or allied subjects.

The second half of the second volume opens with a consideration of the abnormalities and diseases of the fœtus during pregnancy. The first chapter on Extra-uterine Gestation is written by R. Werth and extends to some 360 pages. It is a monograph of the greatest value in which the whole subject is discussed in great detail and with a commendable appreciation of the work of others. In a handbook which contains many articles of the greatest interest this one is pre-eminent for its comprehensiveness and clearness. The author is certainly a master of his subject. The diseases of the membranes of the ovum are dealt with by Seitz who also discusses the affections of the placenta, including tubercle and syphilis and anomalies of the cord. Premature detachment of the normally and abnormally situated placenta is described by Hofmeier in the following chapters. His well-known views as regards the origin of placenta prævia are given at length and this chapter is worthy of careful study, illustrated as it is by a number of important drawings.

The next section on the changes occurring in the fœtus and placenta after the death of the ovum and missed labour and abortion is from the pen of Seitz. He also describes the etiology and mechanism of abortion and premature labour, which is further discussed by Chazan in the following chapter entitled, "The Occurrence, Course, and Treatment of Abortion" Here, again, there is necessarily some overlapping. The last chapter, by Schaeffer, is on Injuries, Traumatisms, and Operations during Pregnancy.

One of the chief features of the book is the very complete list of references which is given at the end of each article, and these should prove of great assistance to many workers on the various subjects. The whole well maintains the high standard set in the first volume and we hope that the remaining volume may follow these two as rapidly as possible. The book is one that should be in the possession of everyone engaged in teaching obstetric medicine.

JOURNALS AND MAGAZINES.

The Bio-Chemical Journal. Edited by BENJAMIN MOORE, M.A., D.Sc., and EDWARD WHITLEY, M.A. Vol. I. Nos. 6 and 7. June, 1906. Published by the Bio-Chemical Department, Johnston Laboratories, University of Liverpool; issued monthly. Price 15*s.* per volume.—This part contains the following articles: 1. Secretions by the Renal Tubules in the Frog, by F. A. Bainbridge, M.D. Cantab., and A. P. Beddard, M.D. Cantab. The authors, as the result of their experiments, suggest as a working hypothesis in regard to the secretions of urine that both the glomerular and tubular epithelia definitely secrete urine and in all probability both can secrete similar constituents in solution. When the quantity of fluid to be secreted from the blood is comparatively small the urine represents the secretions of the tubules because the epithelium covering the glomeruli is insignificant in extent as compared with that of the tubules, but when large quantities of water and salts have to be passed out the glomeruli are the active agents. During saline diuresis the urine approximates more and more to the composition of the blood *minus* proteid, whereby the maximal amount of material is excreted with minimal expenditure of energy by the kidney cells. Increased blood-flow facilitates the discharge of fluid by the glomeruli, but this can take place independently of the vascular changes. 2. A Study of the Pathological Variations in the Acidity of the Gastric Contents, especially in relation to malignant disease, by Benjamin Moore, D.Sc., W. Alexander, M.D. R.U.I., R. E. Kelly, M.D. Liverp., and Herbert E. Roaf, M.D. Toronto. These observers find that the percentage of hydrochloric acid is very sensitive to the general condition of the body and is generally reduced in all cases of illness or enfeeblement. In malignant disease the drop in acidity is especially pronounced and in the majority of cases free hydrochloric acid is entirely absent; the reasons of this are given in detail. 3. A Clinical Method of Hæmalkalimetry, with applications to determination of the reactivity of the inorganic salts of the serum in malignant disease and other conditions, by Benjamin Moore, D.Sc., and Fred. P. Wilson, M.B. Vict., an article containing the results of much patient research. 4. The Physiological Action of Ethyl Chloride, Bromide, and Iodide, and of Somnoform, by W. Webster, M.D., of Winnipeg. 5. The Effects of Antitoxic and Anti-bacterial Sera on the Opsonic Powers of the Blood, by Warrington Yorke, M.B. Liverp., and C. Harold Smith, M.B. Liverp. 6. A Study of the Influence of Nitrite of Sodium on Animal Metabolism, by N. F. Surveyor, B.Sc.

The Ophthalmoscope. Vol. IV., No. 7, July 1st, 1906. Edited by SYDNEY STEPHENSON (London) and CHARLES OLIVER (Philadelphia). Sub-editor, C. DEVEREUX MARSHALL. London: Pulman and Sons. Price 1*s.*—The contents of this number of the *Ophthalmoscope* are: 1. An article by T. Harrison Butler, M.D. Oxon., describing two new operations for Trichiasis. In one of these the misplaced row of lashes with their follicles is excised and a portion of the mucous membrane of the lower lip is adapted to the wound. No sutures are employed. In the other a modified Spencer Watson operation is performed, a triangular portion of the skin flap is removed from the upper border, which border is sutured to the skin above carrying with it the misplaced cilia. The gap left below is filled up with mucous membrane from the lip. 2. The Use of Adrenalin in Spring Catarrh, by Harold C. Grimsdale, F.R.C.S. Eng. 3. Professor R. W. Doyne describes a case of Retinitis Circinata which is illustrated by a chromolithograph. 4. Mr. Richard Gompertz supplies a note on a case of Albuminuric Retinitis simulating Optic Neuritis. 5. A translation by Dr. Percival Hay of a case described by Dr. Segalowitz of Stuttgart is given in which a Pigmentary Nævus of the Choroid was observed in a girl, aged 11 years. In addition to one large mass there were 25 other smaller ones. 6. A description of a New Binocular Coupe with Electric Light, devised by Dr. Berger. In addition to extracts and notes on current literature there is a symposium upon Cataract Extraction, in the course of which the opinions of Professor Fuchs, Professor Haab, Professor Uhthoff, and Professor Axenfeld are given.

The Quarterly Journal of Microscopical Science. Edited by E. RAY LANKESTER, F.R.S., ADAM SEDGWICK, F.R.S., W. F. R. WELDON, F.R.S., and SYDNEY J. HICKSON, F.R.S. With lithographic plates and figures in the text. Vol. L., Parts I. and II. New Series, Nos. 197 and 198. April and June, 1906. London: J. and A. Churchill. Price 10*s.* net each.—The articles contained in the April part (the first quarterly part of a new volume) are: 1. The Life-cycle of Diplodina (Cystobia) Irregularis (Minchin), together with Observations on other Neogamous or Early Conjugating Gregarines, by H. M. Woodcock, D.Sc. Lond. The diplodina irregularis is a gregarine that is parasitic in holothuria forskali, the "cotton spinner" of the south-western coast of England; another, diplodina Minchinii, Woodcock, is parasitic in cucumaria pentactes and cucumaria planci. The diplodina irregularis lives either in the lumen of, or attached to, the blood-vessels. It is never free in the cœlom. The diplodina Minchinii inhabits the respiratory trees. It is never in the intestinal vascular system. The former enters the host by the mouth and the latter by the cloacal aperture. The gregariniform adults of both species are ovoid and motionless. Each adult is really a couple, diplodina being a neogamous gregarine, or one in which precocious association occurs. The cytoplasm has a typical gregarinoid structure. The nucleus possesses a distinct chromatic reticulum in which is suspended a single karyosome. With growth the karyosome becomes vacuolated and divides up in the nucleoplasm. The fragments become incorporated with the chromatin of the nucleoplasm. The earliest nuclear divisions are completely amitotic. All the cytoplasm is utilised to form the gametes or primary sporoblasts. Spore and sporozoite formation in diplodina irregularis follows the usual plan of development. 2. The Anatomy of Oncholaimus Vulgaris, Bast., with Notes on Two Parasitic Nematodes, by F. H. Stewart, M.A., B.Sc. St. And., M.B. Edin., Lieutenant, I.M.S. The oncholaimus vulgaris is a free-living nematode and its structure is compared with a parasitic form ascaris clavata, Rud., and Lieutenant Stewart also describes an embryo of a parasite to connect the two, if possible. 3. The Hæmoflagellates: a Review of Present Knowledge relating to the Trypanosomes and Allied Forms, by H. M. Woodcock, D.Sc. Lond., with figures in the text. This is the first part of a long and carefully drawn-up memoir by Dr. Woodcock on the blood parasites belonging to the class mastigophora which are found in the blood of vertebrate animals, opening up or extending many lines of inquiry that are of far-reaching interest in regard to the possible production and development of infectious disease in man and various vertebrate animals.—The number for June contains three memoirs. 1. The Hæmoflagellates, a Review of Present Knowledge relating to the Trypanosomes and Allied Forms, by H. M. Woodcock, D.Sc. Lond., with 41 text figures. This memoir is a continuation of one in the preceding part and describes the multiplication of these hæmatozoa; the life cycle of trypanosoma Ziemanni as compared with that of trypanomorpha; an account of the Leishman-Donovan-Wright bodies; their phylogeny and evolution, their systematic enumeration, and their relation to the spirochætæ from which the author regards them as being widely separated. There is also appended to the memoir an excellent bibliography of no less than 152 separate papers, works, and articles devoted to the consideration of these and allied blood parasites. 2. Notes on the Development, Structure, and Origin of the Median and Paired Fins of Fish, by Edwin S. Goodrich, F.R.S., with five plates. Mr. Goodrich shows that the development of the median dorsal fins is essentially similar to that of the paired fins. They, like the paired fins, arise as longitudinal folds into which grow buds from the myotomes. Fourteen or sixteen myotomes contribute to the fin each one muscle-bud along the greater part of the dorsal fin; each muscle-bud becomes converted into one radial muscle. The nerve plexus of the fins is composed of intertwining sensory fibres, along or through which the motor fibres proceed to their destination without mixing with those of other segments. There is probably no real motor plexus but the motor nerves may be gathered together with more or less longitudinal *collectors* and become again sorted out on reaching the musculature. Such collectors are found at the base of the dorsal fins. It was determined with absolute certainty that the stimulation of one nerve does not produce a general contraction of the muscles of the fin but only of a limited portion of the musculature corresponding in position to the nerve. The plates give good representations of the distribution of the spinal nerves distributed to the fins. 3. Preliminary Account of a New Organ in Periplaneta Orientalis, by Ruth M. Harrison, Lady Margaret Hall, Oxford, with a plate. The organ is bilobed, of gland-like structure, a lobe lying on each side of the nerve cord between the fifth and sixth abdominal ganglia. It opens below to the exterior by a single aperture on the ventral surface of the animal between the sixth and seventh sternites. It is found in both sexes and in the male measures about two millimetres in length.

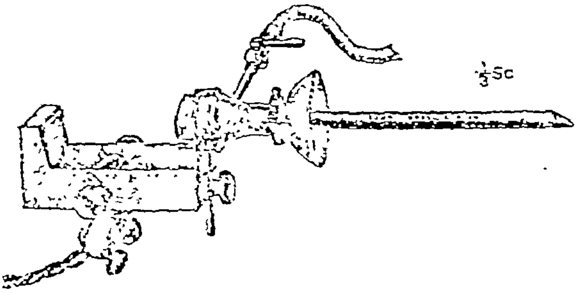
Biochemische Zeitschrift. Parts I. and II.—The continually increasing importance of a right understanding of the chemical processes that accompany manifestations of life has led to the formation of a special department of chemistry to which the term "biochemistry" has been applied. The

Germans as usual, patient and persevering, are attacking the problems that are presenting themselves with the greatest energy. That their labours may not only be preserved but may also be readily accessible and that future inquirers may not have to hunt through many volumes and pages of journals largely devoted to collateral subjects, a journal has been established with the title of "Biochemische Zeitschrift" under the editorship of Professor C. Neuberg of Berlin and we have received the first and second parts which have been published in June of the present year. The topics the consideration of which will be embraced in the journal are various, the prospectus stating that the editor means to include physiological and pathological, as well as physical chemistry, the physiology of plants, bacteriology, inquiries into the nature of immunity, pharmacology, experimental pathology, veterinary investigations, agricultural work, and the like which offer a sufficiently wide field of research. Many leading names are to be found in the list of promised contributors, such as those of Bang, Blumenthal, Galeotti, Hamburger, Kumagawa, Liebermann, Mandel, Michaelis, Nernst, Salaskin, Starling, Traube, Vandevelde, and others; those who particularly coöperate with Professor Neuberg being Buchner, Ehrlich, C. von Noorden, E. Salkowski, and Zuntz. The publisher is Julius Springer of Berlin and the price of each volume, which will consist of six parts, is 12*s.*

New Inventions.

A MODIFICATION OF LEITER'S URETHROSCOPE.

In common with many of my fellow surgeons I have for some years past been in the habit of using the instrument designed by Leiter of Vienna for illuminating the urethra. Although this instrument is admirable in many respects I have lately been using a modified form (*vide* illustration), and its superiority is so marked that I venture to bring it to the notice of my colleagues. The illumination (which when examining a dark red canal can never be too great) has been much increased by the juxtaposition of a high candle power lamp and a condensing lens which concentrates nearly all the light obtainable from one side of the lamp upon the upper part of the reflecting mirror. This condensing lens greatly increases the amount of light obtainable and when used in conjunction with the special lamp and set at its proper angle and distance from the mirror gives such a strong white light that the texture of a piece of cloth or the convolutions on the skin of one's finger can be instantly and easily distinguished at the end of a long urethral tube. In Leiter's model only comparatively few of the diverging rays are utilised—viz., those which fall on a small area at the upper part of the mirror. In the new instrument the rays from one side of the lamp are concentrated on this spot by means of the lens. This area, which should be of about the size of a sixpenny-piece, should have one-third of the circle missing—i.e., the rays passing over the top of the mirror. The pattern of the pencil of light thrown into the cannula can easily be seen on the glass window of the nose-piece (it should be of a size slightly larger than the diameter of the urethral tube). The handle has been dispensed with, as in Fenwick's model, for although preferred by some for a simple examination it is better to grasp the body of the urethroscope when any instrumentation through the cannula is necessary. The cannula is thus much more under the direct control of the hand and the presence of the handle affects the balance and the delicacy of the manipulations. The square shape of the modified instrument affords a firmer hold and one of the projecting screws of the lens carrier, falling naturally between the first and second fingers of the hand, a perfect grip and balance are obtained. The mirror can be moved freely, and when the position reflecting the maximum illumination down the speculum has been found it can be fastened firmly in place by means of a small screw-head projecting behind it upon the back of the instrument and therefore well out of the line of sight. In the old model the mirror, which was usually kept more or less loose for focussing purposes, frequently moved whilst operating by its coming into contact with cotton-holders, forceps, &c., thus plunging the part into darkness at a critical moment. All minor details have been carefully arranged. The window of the nose-piece, which now can be opened at will by a spring arrangement, was designed by me about ten years ago; it is now fitted to all Leiter's models, has the spring catch on the right side as the urethroscope is held with the left hand in all intra-urethral manipulations; the lamp has been obliquely placed and the filament arranged to obtain the best possible result. Those who have urethroscopes of Leiter's or Fenwick's pattern can have the condensing lens and special lamp fitted to them; the illumination is greatly increased by these means, and the lamps are quite inexpensive. The new instrument is fitted with von Antal's arrangement for distending the urethra with air. I would like to mention also that my friends to whom I have shown or lent the instrument have stated that they had hitherto been working in a comparatively dim light and that this illumination was quite a revelation to them. I have to thank Messrs. Down Brothers for so successfully carrying out my ideas and for producing an instrument which is not only simple and handy but practical and efficient, and which will go a long way towards popularising this method of treating chronic urethral diseases.

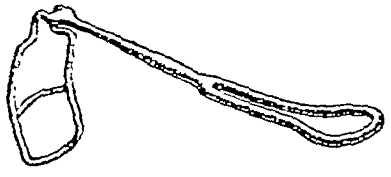


W. Wyndham Powell, F.R.C.S. Eng.

Cavendish-place, W.

A NEW RETRACTOR.

This retractor, made for me in two sizes by Messrs. White and Wright of Liverpool, is designed for use in pelvic operations but it may be of service in almost any abdominal procedure where the retraction of important organs is necessary. It is very light, being made of stout wire, shaped as shown in the figure. I have found it very useful in holding forward the uterus to enable me to secure bleeding points in the pouch of Douglas after the removal of an adherent ovary and tube.



Liverpool. W. Blair Bell, M.D., B S Lond.

Sanatoriums for Workers.—On July 14th Princess Christian laid the foundation stone of the first sanatorium to be erected by the National Association for the Establishment and Maintenance of Sanatoria for Workers suffering from Tuberculosis. The site of the building is at Benenden, Kent, where Her Royal Highness was received by Mr. C. H. Garland, the chairman of the association, and by the honorary officers. In the course of the address to Her Royal Highness Mr. Garland stated: "The sanatorium is the first of what we hope will be a number, destined to supply the wants of the workers who are suffering from tuberculosis. Apart from the accommodation for pauper cases there are not more than 3000 beds provided for the open-air treatment of consumption in this country. We have secured an estate of 250 acres and the present building is placed at a height of 230 feet above the sea level, on a slope that faces south-westward, and, as your Royal Highness is able to see, the outlook is extensive and beautiful. We are assured by our expert advisers that it fulfils all the essential requirements of a sanatorium site." The service was conducted by the Bishop of Dover.

THE LANCET.

LONDON: SATURDAY, JULY 21, 1906.

Should Nurses be Registered?

THE question of the nature and amount of the recognition to be extended to duly trained nurses is one which has greatly exercised the minds of many estimable people, both in and out of Parliament, and on it, there can be no doubt, different opinions may easily be supported by at least a semblance of argument. Medical men, for example, are known to be quite divided in opinion upon the matter. A large proportion of "fully trained" nurses maintain, and many of the matrons and other ladies who have been responsible for their training maintain perhaps even more strongly, that the instruction which they have received is of such a character as to deserve recognition and even protection from the State, in order that the public, as in the case of the medical profession, may at least be enabled to distinguish qualified from unqualified nurses when, if such be their pleasure, they may give their confidence only to the former. A registration by the State and a registration by the Royal British Nurses' Association have each had their advocates, advocates of whom it may, perhaps, be said that the so-called "claims" of the nurses have not been wholly free from a tendency to obscure, in their minds, the convenience and welfare of the institutions or classes by which nurses are chiefly employed. We do not in the least degree blame the champions in question for aiming at all that they can get, or even at a little more than is likely to be conceded to them; but our very tolerance of this position renders it the more necessary that the demands which have been put forth on behalf of nurses should be somewhat jealously scrutinised and that the consequences likely to follow from granting them without reserve should be thoroughly understood by all who are concerned.

A very important difference between the sexes, which in this particular instance should certainly not be overlooked, arises from the fact that a man, who becomes qualified as a member of any profession or calling, usually depends upon it for his livelihood for the remainder of his days, and continues to practise it, with the necessary consequence that his knowledge is kept alive and in working order. A woman, on the other hand, is always liable to be diverted from any special occupation by marriage and by consequent claims of domestic and maternal duties, and it is evident that in a calling like nursing, which affords only a slender remuneration and makes close and constant demands upon the time, it would seldom be possible for a married woman to continue its practice. If every trained nurse were put upon a State register, which was supposed to afford proof of her fitness for the duties of her calling, it would inevitably happen that a certain, even a large, proportion of the persons so registered would soon abandon that occupation on account of the claims of marriage, and would thus, either temporarily or permanently, fall out of the ranks of the calling which they had embraced. A certain proportion of them would afterwards be compelled, by widowhood or by adverse circumstances, to seek to return to their original pursuit; and any kind of professional register which failed to distinguish between nurses who had continued in practice, whose knowledge had been kept up to the high-water mark by regular exercise, and nurses who had been effectively instructed at some remote period and had since had opportunities of forgetting whatever they had known, would certainly be a document calculated in some instances to mislead. On this ground alone, if on no other, we must agree with the "Memorandum" issued by the Central Hospital Council for London in its declaration that registration, as ordinarily understood, would fail to enable the public, when engaging the services of a nurse, to distinguish between one who was efficient and one who was not. It would, of course, fail still more completely in enabling the public to discover the presence or absence of the special qualities or the special experience which render a nurse peculiarly fit for the charge of certain classes of cases, as, for instance, for the care of children or of the aged. A medical man, in selecting a nurse for a patient, would still have to be guided either by his own previous experience of her work or else by the description of her character and capabilities which he received from the responsible official of the hospital, society, or other organisation with which she was connected, for this sort of information could not be supplied by any official register.

The "Memorandum" of the Central Hospital Council, to which we have referred above and which bears on behalf of the council the signature of Sir HENRY HARBEN as chairman, is distinguished by the common sense and practical shrewdness naturally to be expected from that strong man and capable organiser; and it forcibly calls attention to the effects which would follow if some of the more exaggerated claims which have been made on behalf of "trained" nurses were admitted by the legislature. The "Memorandum" states that Sir VICTOR HORSLEY and Dr. LANGLEY BROWNE, speaking for the British Medical Association before the Select Committee of the House of Commons, suggested that it should be a legal offence for any woman to engage in nursing who had not been *fully* trained, and it supplies arguments for disagreeing with the views thus expressed. For it points out that, if the law were as the representatives of the British Medical Association would have it, a very large number of nurses, many of whom are giving satisfaction to their employers and to the public, would be prevented from earning their livelihood. It points out, further, that, while the work of some imperfectly trained nurses is bad, this is not true of the greater number of them, while the inferiority of service often arises from causes quite unconnected with any lack of technical training. Again, it may often be of importance to the poor to be able to obtain the services of a nurse who is willing to accept a lower rate of pay than is demanded by the fully trained, a position that could not be considered under a registration scheme.

The authors of the "Memorandum" have not been content with merely negative criticism and, after calling attention to the defects which would be inseparable from any system of registration and to the fallacy inherent in any comparison between the training of a nurse whose knowledge must often be secondary in importance to her personal character and the education of a medical practitioner, they proceed to suggestions for meeting the recommendations in the report of the committee of the House of Commons. That is to say, they show how the employer of a nurse, whether medical man or layman, may satisfy himself as to her training, and they propose also to obviate the alleged difficulty which may arise from a nurse being sometimes unable, owing to a change of officials or other causes, to obtain a record of her training. For the attainment of these objects they recommend that an Official Directory of Nurses should be instituted and maintained by State authority, and that every nurse who had been trained at a training school for nurses not carried on for private gain should be entitled to an entry in this directory, showing her name, the places, dates, and periods of her training, the nature and dates of any certificates which she may have gained, and any hospital appointments which she has subsequently held. Removal of a name from the directory should be consequent upon death, upon conviction of any criminal offence, upon notice that the person concerned had ceased from nursing, or upon failure for a specified time to respond to official communications. The publication of such a directory would, it is maintained, accomplish all that is really necessary, either in the interests of the public or in those of nurses, and would avoid many objectionable complications. The directory would leave each training school at liberty to develop its teaching on the lines best suited to its circumstances. No system of compulsory examination, with its attendant difficulties and evils, would be instituted. The real employer of a nurse—that is to say, the medical practitioner—would be able to ascertain from the directory the bearing of her training upon her fitness for the case for which she was required, while the public could learn whether a nurse's statements as to her training were accurate, and also, in most cases, where to seek for further information if it were desired. No deceptive pledges of efficiency would be given by any public institution, and no woman with an aptitude for nursing would be hindered from affording to the sick such services as she was able to render and they were willing to accept, or from receiving such modest remuneration for her work as she might be in a position to command. The conditions thus indicated would seem to make for the greatest happiness of the greatest number and, while they would leave the "trained" nurse in undisputed possession of the distinctions which she had earned, would place no artificial difficulties in the path of her humbler, but often not less useful or less willing, sister.

The Adulteration of Imported Food.

AN important decision of the Divisional Court affecting the position of importers of articles of food has now been carried into effect by Alderman Sir J. RITCHIE sitting to re-hear a summons which he recently dismissed subject to the stating of a case for the consideration of the High Court. The summons was taken out by the Customs authorities in respect of the importation of 127 packages of butter by the defendants, Messrs. LONSDALE & Co., Limited, which were adulterated with foreign fat but were not marked in accordance with Section 1 of the Sale of Food and Drugs Act, 1899, so as to indicate their character. The defendants at the original hearing, which took place in January, did not deny or dispute the fact that the butter was not pure butter, but pleaded in defence that they had purchased it under a warranty that it was pure and of a kind known as control butter—that is to say, that it was produced under the control of the Dutch Government. As to this, again, there was no dispute, and the honesty and good faith of the defendants in the matter were in no way doubted, but the point was taken that the defence of warranty from the vendor, which can be raised under the Sale of Food and Drugs Act where the parties to the transaction both trade in the United Kingdom, does not apply to the case of an importer buying from a person abroad. The Alderman, when he heard the summons originally, was of opinion that the defence of purchase under warranty applied to both classes of case, but the Customs authorities, not being satisfied, appealed and the Divisional Court has since upheld their contention. At the recent re-hearing it was intimated on behalf of the defendants that they had other defences which they were prepared to raise but which they had abandoned at the first hearing in order to rely upon the defence which had now been decided to be bad. They were therefore willing to plead guilty to an offence under the Act, but they urged through their counsel that it was of a technical character, committed in ignorance of the construction which would be put upon the law, and relying upon a false warranty given to them by dishonest persons. The Customs authorities did not press the matter or dispute the good faith of the defendants and the Alderman acceded to the views of both parties and inflicted a nominal penalty of 10*s.* with £3 3*s.* costs. Upon this the defendants are to be congratulated. They had the protection afforded by a good reputation for honest trade and it would have been a hardship for them had they been treated as dangerous culprits when they were no doubt the victims of unscrupulous and deceitful dealers abroad. At the same time the public are to be congratulated also that the law stands as the Divisional Court has decided, for the distinction between the purchase of food materials at home and the responsibility attaching to the obtaining of similar goods abroad is not an unreasonable one. When the sale takes place in the United Kingdom a fraudulent or an untrue warranty is likely to bring serious consequences upon the head of him who gives it and this fact is calculated to prevent its being given. The institution of legal proceedings, whether civil or not, against a firm abroad is a more difficult and a more costly matter, and the probable immunity is not unlikely to tempt dishonest people. Importers, moreover, usually deal upon a tolerably large scale, and if, in the absence of protection by a warranty, they find it advisable to examine independently the goods which they buy they are likely to be able to afford the cost of doing so. In any case such independent examination is a protection to their customers. In this particular instance it may be pointed out that the Customs authorities instituted the proceedings, so that the defendants presumably had not had the opportunity of testing for themselves in this country the quality of the butter consigned to them.

Motor Traffic Offences.

EVERYONE is saying perpetually that the motor omnibus has come to stay. Public opinion, however, may well decide otherwise, and be entitled to do so, if the motor vehicles now upon the London streets are not improved in many fundamental directions. Many of us have learned with some surprise during the last few days, days during which the papers have reported sad accidents owing to motor omnibuses, that the companies owning these vehicles have it entirely in their own hands to crowd suddenly any hitherto peaceful roadway with a busy service of noisy, petrol-reeking wagons, shaking the houses to their foundations, filling the air with an abominable stench, disseminating around them clouds of dust, and raising a clatter with their gear which makes all rest, all work, all peace alike impossible to those who live upon the track along which they pound their vehement and offensive way. The state of things now admitted to exist in some of the best residential parts of London is intolerable and opposed altogether to common justice. It is said that at the present time the public is undergoing an unpleasantness incidental to an experimental stage. But why should this experimental stage be inflicted on the public in this nauseous manner? If the omnibuses are not in a state to be put on the thoroughfares they should be excluded until they are perfected. Surely the cheap and expeditious way with which the motor omnibus performs its journey cannot be held to compensate for the foul smells which it leaves behind it and the hideous scroop of its brakes and gearing. We are told that the motor omnibus as a means of locomotion is a success, a proof of which is seen in the great numbers of people who patronise this method of travelling. We have no doubt at all that many people find the motor omnibus convenient, cheap, and quick for getting to and from their places of business, but the very places of business themselves threaten to be shut up if the evil odours and noises which it scatters far and wide are not soon remedied. We appeal to the motor engineer to turn out something better than he is doing now or disaster must fall upon his industry. And if the engineer can do no better than the present examples of construction show we hope for a prompt administration of the laws which protect the well-being and health of the community.

We have frequently called attention in these columns to the prejudice to the health and the comfort of the people of London which was threatened by the impending change of horse traffic to motor traffic At first sight it might have been thought that this change would improve the sanitary condition of the streets. It is doubtful whether at present this is the case. The old pollution arising from the presence of hard-worked horses in the streets threatens to give way to a new pollution which may have even more marked and more widespread prejudicial effects on health. We cannot forget that the combustion of petrol in the motor engine is seldom perfect and the output of poisonous gases, amongst which may be included carbon monoxide, is considerable. Besides there are quite large quantities of petrol vapour constantl escaping into the streets and petrol is undoubtedly a poison Then there are the fumes arising from the overheating o the lubricating oil, an event, we believe, which i regarded as a sign that the driver is not the master o his engines. Lastly, there is the intolerable noise of th engines and the gear, with the torture that they mean to th nervous, the delicate, and the invalid. Altogether, the con clusion cannot be resisted that the motor omnibus—in it present shape, at all events—ought never to have been pu upon the streets, and unless improvements are rapidly mad which remove these intensely disagreeable characteristic they should be refused the qualification of commo carriers on the KING'S high road. The facts that they ar offensive to our senses and destructive to property make u a serious indictment which calls for serious treatment. Th fact that they are a menace to health is a still more urgen matter. We appeal again to the motor engineer to desig something better. We are certain that he has not done hi best yet and we have a shrewd idea that the reason of thi is that he is not given sufficiently liberal estimates. Al the amenities of life must not be outraged that so-calle pioneers of quick transit may pocket dividends.

Mr. Haldane's New Army Reforn Scheme.

ON Thursday, July 12th, Mr. HALDANE expounded hi new army policy and war scheme to a very full House in speech of nearly three hours' duration. The speech wa an outspoken and powerful statement of a proposal to increase the efficiency of our army and yet to economise in the sums to be provided for its upkeep by certain important reductions. As regards the Army Medical Service and army medical matters we are glad to notice that the War Minister adopted an earnest and sympathetic tone. The problems involved in Mr. HALDANE'S system of army reorganisation are so many and so complicated that it is not easy to get an accurate and at the same time comprehensive view of his proposals. There is, of course, a broad and general political side to all schemes of army reform, with which we are not directly concerned, except that an efficient army means security and peace, while insecurity or war necessarily has the most disastrous effect upon scientific progress. But with the health of the army and whatever appertains thereto we have direct business. It is not so easy as might at first sight appear to keep the distinctions between the general subject and the particular heading apart; they have a tendency to overlap. As a case in point, Mr. HALDANE dwelt with some legitimate pride and satisfaction on the fact that the South African War showed the resources of our Empire, and proved that so long as certain conditions remain fulfilled we may rely in a supreme emergency on the whole strength of that Empire. Well, this may be so, but the war also proved to all medical men the complete lack of proper provision made by the Government and by the predecessors of the Government for proper medical organisation. It is not the keenness and willingness of people to fight, but their preparedness for war that is the problem; and we make bold to say that our medical service is not properly prepared and organised at the present time to take the part that it should in any really big war. What will be required in future is not so much, perhaps, a defensive home army as the organisation of some scheme for an Imperial army with an Imperial medical service as a component part thereof, which shall be more in harmony with the new and altered conditions of the British Empire. We do not despair of some scheme of this kind being initiated at the forthcoming conference of the colonial delegates next year. Mr HALDANE spoke words of admirable sense in his references to the health of the army, and the views and intentions of the Government in regard to the medical, sanitary, and hospital services in time of war will have been carefully read and studied by all concerned. He enumerated briefly but correctly the chief sources of disease in an army on field service, and stated how it was proposed to deal with them respectively, giving a very brief outline of a scheme, already partly in operation, drawn up for that purpose by Sir ALFRED H. KEOGH, the Director General of the Army Medical Service. Taking all this into consideration we find that Mr. HALDANE'S proposals as a whole are indicative of a sincere and earnest purpose to improve our army as a fighting machine, to insure for it better medical equipment, and at the same time to save the public purse. It is inevitable, however, that his scheme should come in for severe criticism from military authorities.

Annotations.

"Ne quid nimis."

THE NEW PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

AT a meeting of the Council of the Royal College of Surgeons of England held on July 13th Mr Henry Morris was elected President and Mr Edmund Owen and Mr Rickman J. Godlee were appointed Vice-Presidents. To Mr Morris, who has thus attained the highest honour which it is in the power of the corporation to which he belongs to bestow, we offer our hearty congratulations. Mr Morris is well known as an able and energetic worker in the field of surgery in general, while he has made for himself a wide-spread reputation in that department of surgical science which deals with the genito-urinary apparatus. He has won for himself reward in the hearty recognition of the value of his work accorded by his brother practitioners, while the public has been prompt to recognise in him a friend of exceptional skill. His practical and enthusiastic interest in the cause of medical education, especially the education of the London student, was shown by his recent gift of the sum of £1000 to the endowment fund of the Middlesex Hospital Medical School. Mr. Morris's views upon medical education are worthy of the consideration of everyone who is interested in the subject, and though we ourselves have not always been able to see eye to eye with him, yet we must acknowledge his whole-hearted wish for the improvement and reform of medical education in London. It will be remembered how ably he set forth his point of view in the address delivered by him before the Medical Society of London on May 15th, 1905. A strong man, one who knows clearly what he wants and who can explain his views in simple well-turned sentences, Mr Morris should prove an able presiding officer of the corporation which has entrusted its destinies for the present to his hands. In offering him our best wishes in his new post we also take the opportunity of congratulating Mr Tweedy upon the successful conduct of the affairs of the College during the long period of his administration which has now come to an end. Mr Tweedy's labours as President of the College were complicated by the fact that he was during a part of the same period President of the Ophthalmological Society, but he allowed no call, private or official, to stand between him and the energetic discharge of his duties towards the College.

SERVIA AND THE CHICAGO MEAT SCANDAL.

IN the report by our Special Sanitary Commissioner on the Chicago stockyards which was published on Jan. 7th, 1905, there occurs the following paragraph: "Several years ago when in Servia, I was consulted by the authorities as to what could be done to improve the material resources of the country. The founders of both rival dynasties, the Kara-georgewitch and the Obrenovitch houses, had been engaged in the rearing of pigs. Indeed, pigs and prunes are the principal products of the country, so I urged that instead of sending at great cost living pigs to the Hungarian markets a model slaughter house should be constructed according to the latest principles of sanitary science. Close to Belgrade, either on the banks of the Save or of the Danube, there is an abundance of vacant space admirably suited for such a purpose. Here shambles made mainly with iron and glass, bathed in daylight and sunlight, with double ventilating roofs, could be constructed. Of course, there would be good laboratories for bacteriological research and microscopical examination. With such measures and precautions the products might attract many purchasers by reason of the security which enlightened scientific and State control would insure. Is it now too late for such arguments to be applied at Chicago?" It is obvious that much trouble might have been saved if the arguments as suggested had been applied at the Chicago stockyards. According to the *Daily Mail*, the imports of tinned meats to the Albert Docks, London, from Boston and New Orleans, which consist of Chicago products, amounted in June, 1905, to 27,000 cases; but there were only 4000 cases in June, 1905. In July, 1905, 24,000 cases came over; but in July this year not a single case was landed. Not only, however, is the Chicago trade with England thus falling off but it has been stated in several papers that Servia is going to enter the lists as a competing power. According to the *Neue Freie Presse* English capitalists are expected to come to the rescue of Servia in the difficulties which arise as a consequence of the constant conflict between that small State and her powerful neighbour Austria. Whenever Servia fails to bow to the exigencies of Austrian diplomacy some form of cattle disease and swine plague is found to prevail and the Austro-Hungarian frontier is closed to the Servian hogs or cattle. The principal trade of the country is thus paralysed. Therefore it would be a great advantage for Servia to do its own slaughtering of beasts and to preserve and to pack its own meat. For these reasons it is stated that a group of English capitalists are about to visit Belgrade with the view of making arrangements so as to found a new stockyard and packing town near Belgrade. Certainly there is an opening for the creation of this industry on scientific lines, the first object being to provide food products in such a manner that no sort of suspicion as to their wholesomeness could arise. This the Servian State might have undertaken to its own profit, direct and indirect, without interfering with any vested interest, for these do not exist in that somewhat primitive country. It would be difficult in making the attempt to find a better moment—a better psychological moment, as Prince Bismarck would have said—than the present. But the Servian Government, in its eagerness to secure such assistance as may reduce defendants presumably had not had the opportunity of testing for themselves in this country the quality of the butter consigned to them.

Motor Traffic Offences.

EVERYONE is saying perpetually that the motor omnibus has come to stay. Public opinion, however, may well decide otherwise, and be entitled to do so, if the motor vehicles now upon the London streets are not improved in many fundamental directions. Many of us have learned with some surprise during the last few days, days during which the papers have reported sad accidents owing to motor omnibuses, that the companies owning these vehicles have it entirely in their own hands to crowd suddenly any hitherto peaceful roadway with a busy service of noisy, petrol-reeking wagons, shaking the houses to their foundations, filling the air with an abominable stench, disseminating around them clouds of dust, and raising a clatter with their gear which makes all rest, all work, all peace alike impossible to those who live upon the track along which they pound their vehement and offensive way. The state of things now admitted to exist in some of the best residential parts of London is intolerable and opposed altogether to common justice. It is said that at the present time the public is undergoing an unpleasantness incidental to an experimental stage. But why should this experimental stage be inflicted on the public in this nauseous manner? If the omnibuses are not in a state to be put on the thoroughfares they should be excluded until they are perfected. Surely the cheap and expeditious way with which the motor omnibus performs its journey cannot be held to compensate for the foul smells which it leaves behind it and the hideous scroop of its brakes and gearing. We are told that the motor omnibus as a means of locomotion is a success, a proof of which is seen in the great numbers of people who patronise this method of travelling. We have no doubt at all that many people find the motor omnibus convenient, cheap, and quick for getting to and from their places of business, but the very places of business themselves threaten to be shut up if the evil odours and noises which it scatters far and wide are not soon remedied. We appeal to the motor engineer to turn out something better than he is doing now or disaster must fall upon his industry. And if the engineer can do no better than the present examples of construction show we hope for a prompt administration of the laws which protect the well-being and health of the community.

We have frequently called attention in these columns to the prejudice to the health and the comfort of the people of London which was threatened by the impending change of horse traffic to motor traffic. At first sight it might have been thought that this change would improve the sanitary condition of the streets. It is doubtful whether at present this is the case. The old pollution arising from the presence of hard-worked horses in the streets threatens to give way to a new pollution which may have even more marked and more widespread prejudicial effects on health. We cannot forget that the combustion of petrol in the motor engine is seldom perfect and the output of poisonous gases, amongst which may be included carbon monoxide, is considerable. Besides, there are quite large quantities of petrol vapour constantly escaping into the streets and petrol is undoubtedly a poison. Then there are the fumes arising from the overheating of the lubricating oil, an event, we believe, which is regarded as a sign that the driver is not the master of his engines. Lastly, there is the intolerable noise of the engines and the gear, with the torture that they mean to the nervous, the delicate, and the invalid. Altogether, the conclusion cannot be resisted that the motor omnibus—in its present shape, at all events—ought never to have been put upon the streets, and unless improvements are rapidly made which remove these intensely disagreeable characteristics they should be refused the qualification of common carriers on the KING'S high road. The facts that they are offensive to our senses and destructive to property make up a serious indictment which calls for serious treatment. The fact that they are a menace to health is a still more urgent matter. We appeal again to the motor engineer to design something better. We are certain that he has not done his best yet and we have a shrewd idea that the reason of this is that he is not given sufficiently liberal estimates. All the amenities of life must not be outraged that so-called pioneers of quick transit may pocket dividends.

Mr. Haldane's New Army Reform Scheme.

ON Thursday, July 12th, Mr. HALDANE expounded his new army policy and war scheme to a very full House in a speech of nearly three hours' duration. The speech was an outspoken and powerful statement of a proposal to increase the efficiency of our army and yet to economise in the sums to be provided for its upkeep by certain important reductions. As regards the Army Medical Service and army medical matters we are glad to notice that the War Minister adopted an earnest and sympathetic tone. The problems involved in Mr. HALDANE'S system of army reorganisation are so many and so complicated that it is not easy to get an accurate and at the same time comprehensive view of his proposals. There is, of course, a broad and general political side to all schemes of army reform, with which we are not directly concerned, except that an efficient army means security and peace, while insecurity or war necessarily has the most disastrous effect upon scientific progress. But with the health of the army and whatever appertains thereto we have direct business. It is not so easy as might at first sight appear to keep the distinctions between the general subject and the particular heading apart; they have a tendency to overlap. As a case in point, Mr. HALDANE dwelt with some legitimate pride and satisfaction on the fact that the South African War showed the resources of our Empire, and proved that so long as certain conditions remain fulfilled we may rely in a supreme emergency on the whole strength of that Empire. Well, this may be so, but the war also proved to all medical men the complete lack of proper provision made by the Government and by the predecessors of the Government for proper medical organisation. It is not the keenness and willingness of people to fight, but their preparedness for war that is the problem; and we make bold poor children requiring the benefit of seaside air and for children suffering from pulmonary tuberculosis in its early stages. The Board complains that the guardians also fail to take full advantage of the excellent training which is given to boys on the training-ship *Exmouth*. The guardians of some of the country unions are not so lax in their attention to the best interests of boys under their care and the number of boys from these unions at the *Exmouth* is yearly increasing. It is hoped that as the good work of these institutions becomes better known they will be more appreciated.

TREATMENT OF EPILEPTIFORM NEURALGIA WITH THE X RAYS.

AT a meeting of the Société Médicale des Hôpitaux of Paris on May 4th M. A. Béclère and M. Haret showed a man the subject of left facial paralysis whose face on that side was disfigured with cicatrices. For seven years he had suffered from epileptiform neuralgia and had undergone a number of operations. First, all the teeth on the left side of the upper jaw were extracted in succession. Then the infra-orbital nerve was divided. No relief was afforded. Excision of the Gasserian ganglion was performed and the facial paralysis was a result. The pains disappeared but returned after six or seven months. Then the superior cervical ganglion of the sympathetic nerve was excised. The pains again disappeared but returned after a shorter interval—four or five months. Severe attacks of epileptiform neuralgia occurred from ten to 12 times daily. The pains were felt in the alveolar border of the left superior maxillary bone from which the teeth had been extracted. The x rays were applied through the mouth solely to the painful region, the neighbouring parts being protected by a tube of lead glass (*verre au plomb*). The rays fell on the alveolar border in the position of the first and second molar teeth. They were applied at intervals of a week. After the first and second sittings there was no improvement but after the third the pain diminished and a slight reaction was observed on the border of the upper lip, which had been badly protected. After the fourth sitting, which took place on April 25th, 1905, the pains disappeared and they have not since returned. M. Béclère and M. Haret did not claim to have cured the patient by this treatment but to have produced an interval of immunity of more than a year, a much better result than that given by the severe operations. If the pains recurred the treatment could be repeated. They did not assert that all cases of facial neuralgia would give such a good result but they thought that before exposing a patient to the dangers of such an operation as excision of the Gasserian ganglion this simple method of treatment should be tried.

NURSES AND THE PUBLIC VIEW OF THEIR WORK.

THERE can be little doubt that the popular views on nursing are liable to be erroneous and must be the cause of no little annoyance to those who follow that calling. On the one hand, there are some who refer to the nurse in terms of fulsome adulation as combining the qualities of the heroine with the devotion and self-sacrifice of the saint and in every way exaggerate the importance of her place in the scheme of treatment, forgetting that the duties of the true nurse are to minister to the comfort of her patient and religiously to carry out the instructions of the practitioner who is in charge of the case. On the other hand, the nurse is too often treated both unkindly and neglectfully by those who, forgetting the arduous and exacting character of her duties, make unreasonable demands upon her time and energies and deny to her that consideration in regard to her own personal health and comfort to which she is justly entitled. Thus, the nurse is not infrequently in private houses expected to be on duty or within call both night and day, to snatch her meals when she can, and to forego some of the necessary rest and exercise without which she cannot hope to remain in health. That conditions perilously near to sweating are not unknown to the nursing staffs of institutions would appear to be the case if the account given of the proceedings of the Aston board of guardians, reported in the issue of the *Birmingham Despatch* of June 27th under the heading of "over-worked nurses," is to be believed. The infirmary committee in the course of a report to the board called attention to the fact that the infirmary was understaffed, pointing out that a probationer nurse was often in charge of more than one ward—that is, of more than 50 patients. A member of the committee, in moving the adoption of the report, pointed out the severe strain upon the night staff of the hospital and stated that the night nurses often had to go without their meals owing to the pressure of their duties. It was proposed that six additional nurses should be appointed so as to have one on night duty for each ward, which would appear to be a reasonable demand, indeed the least compatible with safety. Eventually, after some discussion, it was decided to appoint three additional nurses instead of six. A member of the board who was subsequently interviewed expressed his disappointment that the guardians failed to realise the high pressure at which the nurses worked and also his fear that the incomplete night nursing would be responsible for occurrences which the guardians would deplore, owing to the number of acute cases and of mental cases which required constant attention. It is manifestly unjust, alike to the patients and to the nurses themselves, that too great a number of beds should be assigned to the care of each nurse, so as to render it impossible to carry out effectively the requisite nursing of each patient. The incident illustrates the lack of knowledge of the duties and hours of work of nurses which so generally obtains. It is certainly the duty of those in authority at public institutions and of the heads of private nursing associations to see not only that the nurses carry out their duties satisfactorily but also that they are not over-worked and that they obtain an adequate amount of rest and of outdoor exercise. The altruistic aspects of the profession of medicine and of nursing are likely to invest them with a sentimentality in the minds of certain people who forget that, after all, their exponents are in the majority of cases following them as a means of livelihood and endeavouring to do their duty to the best of their ability and that they deserve a sufficient recompense for their labours and some consideration at the hands of those for whom they often give most unsparingly of their time and ability, not merely from an exalted idea of the nobility of their calling but from a sincere and honest desire to carry out efficiently the duties intrusted to them.

INTEMPERANCE IN THE EIGHTEENTH CENTURY.

A PIONEER of temperance reform, writing in 1734, makes the now familiar complaint as to the recklessness of drinkers and the deadly effects of over-indulgence in liquor. "Though they yearly see a thousand fall at their side," says he, "and ten thousand at their right hand, yet will they not be warned. There is that predominant bewitching of naughtiness in these fiery liquors, as strongly and impetuously carries men on to their certain destruction." The old writer at first sight uses a familiar set of phrases and indulges in what looks like the time honoured exaggerations of the modern anti-alcohol crusade. Yet a closer acquaintance with his "Friendly Admonition to the Drinkers of Brandy" the burden of Austrian pressure on the economic situation, must be very careful not to grant concessions that only cover the financial requirements of the case. This is above all, and first of all, a public health question. Further, and unlike many other public health questions, it is a matter on which the general public feels very strongly. The Chicago scandal has served a good purpose in educating the masses on this subject, a fact proved by the complete collapse of the trade in Chicago tinned meats. Therefore, if the Servian Government does not feel capable of itself undertaking to create the meat industry so much needed in that country it must grant concessions to capitalists, from whatever country they may come, only under the cover of such stipulations as shall absolutely insure that they will adopt the most perfect and scientific health-preserving methods. Our Sanitary Commissioner made suggestions to this effect when called to Belgrade by the Servian Government so as to advise in regard to a scheme for the drainage of the capital. This was some nine years ago. The idea has taken time to ripen but there will not be much cause to regret such delay if good use is made of the extraordinarily favourable opportunity which the Chicago scandal provides for such an enterprise.

UNQUALIFIED DENTAL PRACTICE.

A case of some interest to the dental profession and to the public in general has recently been decided in India. A man named David Lamb, once of Liverpool, and described as a dental surgeon carrying on his "business" at Secunderabad, sued for libel a person named Dr. A. A. Mix for advertising that he was the only qualified dentist in Secunderabad, the plaintiff alleging that the statement was prejudicial to his practice and interests and claiming Rs.1000 damages. The plaintiff, so far as the evidence showed, had never attended any school or university where dentistry is taught; he had apparently spent a period of nine months with a dental practitioner and previously to this was a planter, and on the strength of this training he called himself an American dentist because he claimed that he practised the American system of dentistry, whatever that may mean. He obtained in practice the services of one named Hertz, a Doctor of Dental Surgery, to whom he paid monthly the sum of Rs.450 out of a total takings of Rs.750. On Dr. Hertz leaving the income of the practice underwent a considerable diminution. The defendant, Dr. Mix, was a Doctor of Dental Surgery of Buffalo, U.S.A., and he stated that to call oneself an American dentist the individual must possess the degree of D.D.S. In India there is nothing to prohibit the practice of dental surgery by anyone; the question therefore at issue was mainly the right amount of importance to place on the use by Dr. Mix of the word qualified and evidence was given by two medical practitioners with regard to the generally accepted meaning of the term. In giving his decision the judge held that the advertisement was not a libel and that the publication only referred to the qualifications of a dentist which admittedly the defendant possessed and the plaintiff did not possess. The judge also held that the advertisement had nothing whatever to do with the competency and capabilities of the litigants which the defendant was presumed to possess on account of his qualification and which the plaintiff also might possess in an equal, or even in a greater, degree. The case gives a good insight into the question of unqualified practice and shows the flimsy grounds on which an individual will assume the title of dentist and practise on the unsuspecting public. In India and our colonies we understand that unqualified dental practice is rampant, but unfortunately it is by no means confined to those portions of the empire, for at home the quack and the charlatan thrive despite all the efforts of those interested in trying to enforce the spirit of the Dentists Act. Cases are constantly coming into the law courts and under the notice of the proper practitioners in which not only has bodily harm been done by unqualified people but also exorbitant fees have been obtained under what is nothing more or less than obtaining money under false pretences, and yet the Government makes no effort to amend this altogether unsatisfactory condition of affairs. In the case under notice we think that Dr. Mix's ethics are open to criticism. His assumption of the title of American dentist is unfortunately only in keeping with the action of many other men educated in America who come to practise here and in our colonies. If an individual goes to practise in a foreign land he should conform to the etiquette of the profession in that land. The generally accepted position in this country is for those practising dentistry, whether medically qualified or not, to use the title of "Mr." and not "Dr." A large amount of the ill-feeling that exists towards American graduates practising in this country would cease if they would conform to the etiquette of the profession here and carry out their practice on lines more in keeping with the traditions of an honourable calling.

THE ANNUAL REPORT OF THE METROPOLITAN ASYLUMS BOARD.

The report on the work of the Metropolitan Asylums Board during the year 1905 which has just been published is an important volume of over 300 pages and contains numerous charts and tables showing the movements of infectious disease in London. The work of the Board, as may be known to many of our readers, is very far-reaching, including jurisdiction over 17 infectious hospitals, five asylums for imbeciles, a training ship, 15 schools or homes for certain classes of children, and eight land ambulance stations, besides a service of ambulance steamboats. During the year 27,162 patients passed through the Board's fever hospitals and 72 patients through the small-pox hospitals. The number of cases of scarlet fever treated was 19,362, a larger number than in any previous year since the establishment of the Board's hospitals in 1870. The increase was due not so much to the greater prevalence of the disease as to the increased percentage of persons attacked who now enter the hospitals. In 1890 only 42 per cent. of the cases notified came into hospital. Last year over 88 per cent. were admitted. The death-rates, except in the case of small-pox, compared well with the death-rates of the previous year, those for 1905 being: scarlet fever, 3·3 per cent.; diphtheria, 8·3 per cent.; enteric fever, 13·1 per cent.; other diseases, 6·8 per cent.; and small-pox, 14·5 per cent. Those for 1904 were 3·4, 10·1, 14·6, 9·2, and 6·0 per cent. respectively. The decline in the rate of mortality amongst cases of diphtheria is an extremely important feature in the statistics. In 1893, the year before the disease was treated with antitoxic serum, the death-rate was as high as 30·4 per cent. Since the introduction of the treatment the rate has rapidly declined. At one of the hospitals a record has been kept of the mortality-rates according to the day of disease on which the antitoxic serum treatment was commenced. Of 219 cases treated during the years 1897 to 1905 on the first day of the disease not a single case died, and amongst 1364 treated on the second day of the disease the mortality-rate did not rise above 5·4 per cent., whereas amongst cases not coming under treatment until the fifth day and after the rate has been upwards of 22 per cent. Not for the first time attention is drawn to the apathy displayed by the metropolitan boards of guardians in making use of the homes provided for

Rubner, Berlin N. 4, Hessischestr. 4. The business of the Congress is conducted by the secretary-general, Retired Surgeon-Major Dr. Nietner. The offices are at Berlin W. 9, Eichhornstr. 9.

ANGINA PECTORIS AS AN EARLY SYMPTOM OF ANEURYSM OF THE AORTA.

IN the *Medical Chronicle* for May Professor W. Osler has called attention to cases of aneurysm of the aorta in which angina pectoris is an early symptom. He points out that in aortic aneurysm four kinds of pain may be recognised —pain with the characters of true angina, neuralgic pain (due to pressure on nerves), pain of a dull boring character (which occurs when the chest wall is being eroded), and pain referred to the nerves of the arms or to the præcordial, pectoral, or sterno-mastoid regions. In only a small minority of cases is the pain of a definitely anginal type. Such pain may precede for months or years the appearance of an aneurysm which in the meantime is unsuspected. Professor Osler relates four cases of which the following is an example. A muscular man, aged 51 years, came under observation on March 11th, 1894. He had always enjoyed good health and said that he had never had syphilis. Since October, 1893, he had had attacks of pain in the chest which began a short time after he had gone to bed. The pain was of a dull burning character and situated just beneath the sternum. After a short time it usually passed off and he went to sleep. Then about 4 or 5 A.M. he was awakened with pain and a sense of oppression and he had to sit up in bed. Frequently there was an unpleasant sensation in the back; sometimes the pain left the front and became severe in the back. There was no special anguish or sense of impending death. He could move about during the attacks and motion gave relief. Nitrite of amyl, nitro-glycerine, and the iodides were taken without avail and lately he had been forced to use morphine. On examination he was found to be a healthy-looking man. The pupils and radial pulses were equal. Percussion over the manubrium was clear. The second cardiac sound was accentuated towards the base and was loud and ringing to the right of the sternum. There was no tracheal tugging. The knee-jerks were absent. It was difficult to determine whether there was true angina associated with an organic lesion. The attacks had scarcely the intensity of the genuine form. There was no sweating, change of colour, or immobility. Only two facts suggested an organic basis—accentuation of the second sound and absence of the knee-jerks. Six years later the patient was again seen. The attacks had gradually disappeared, though he had at intervals pains in the chest. There were stridor, diffuse pulsation over the manubrium, diastolic shock, and tracheal tugging.

TRANSPLANTATION OF THYROID GRAFTS INTO THE SKIN.

IT is well known that in myxœdematous conditions ingestion of thyroid material obtained from an animal and administered under any form will to some extent restore the normal condition but the treatment is only palliative and there is a possibility of a kind of tolerance of it being established so that the therapeutic effect is lost. Many attempts have therefore been made to transplant or graft portions of thyroid gland under the skin, but all such endeavours have failed until lately.[1] Professor Charrin of the College of France and M. Christiani have, however, at last solved the problem by improving the operative methods and employing a great many very small portions of thyroid glands taken from animals of the same species and transplanted with the utmost celerity. At a recent meeting of the Paris Academy of Sciences held on July 2nd they showed a young woman who in consequence of having no thyroid gland and showing symptoms of myxœdema had been treated with 34 drops of a thyroid solution every day. After having received 38 thyroid grafts in two operations she was able two years afterwards greatly to reduce the dose of the solution so that she now took only from two to four drops—i.e., 0·10 part by weight instead of 1·50. She has, moreover, become the mother of a normal infant and during her pregnancy the thyroid grafts became enlarged, just as happens with the thyroid gland in pregnancy under normal conditions. The thyroid grafts have preserved their glandular nature. This case seems to point the way to a new method of treatment.

THE LAY TREATMENT OF DISEASE BY MUNICIPALITIES.

A RESOLUTION was adopted by the Bradford division of the British Medical Association on June 12th which is of distinct interest to the medical profession. It runs as follows:—"That in the opinion of this meeting it is highly undesirable that the city council should carry on the treatment of disease for profit through officials at the corporation baths who are not legally qualified medical practitioners, who treat diseases which are not of an epidemic character; that such practice is illegal, the council having no powers authorising them to carry out such treatment." A copy of this resolution has been forwarded to the mayor of the town, to the medical press, and to the General Medical Council, and we are certain that all interested will see the importance of the opinions expressed. Municipalities are only properly prudent and farseeing when they strive to afford facilities for the systematic treatment of disease, but any attempt to substitute lay methods for scientific therapeutics must end in disaster.

THE DISPARITY BETWEEN THE THERAPEUTIC ACTIVITY OF FRESH DRUGS AND OF THEIR PREPARATIONS.

IT has often been pointed out that galenical preparations and active principles are not identical in their therapeutic action with the corresponding fresh drugs. In the April number of the *Répertoire de Pharmacie* M. Perrot instances opium, cinchona, coca, kola nut, digitalis, strophanthus, and the mydriatic group of solanaceous plants as examples of drugs which are not wholly represented by their active principles, morphine, quinine, cocaine, caffeine, digitalin, strophanthin, and atropine. But such active principles are usually of definite composition and their dose is readily ascertained, whereas tinctures, extracts, and other galenical preparations of plants vary considerably in strength and in medicinal action, owing to variations in the crude drugs and in the mode of preparation, and other causes. Some years ago M. Golaz, a Swiss pharmacist, attempted to produce galenical preparations of uniform strength and wholly representative of the crude drug by subjecting the fresh juice of plants to dialysis, but his method does not appear to have been adopted largely. The recent researches of M. Bourquelot and M. Bertrand on the ferments or oxydases present in plants have pointed to a probable way of improving the methods of making galenical preparations. They have shown that the oxydases, when exposed to a high temperature, lose their power of producing changes in the active principles of plants. For example, kola exerts an energetic action in cases of fatigue on the natives of those parts of Africa where it is indigenous, whereas preparations of kola made in Europe from the dried nuts are much less active. M. Perrot found that the fresh nuts and the extract obtained therefrom contain a phenolic compound, kolatine, which exerts an action entirely different from that of caffeine, to which the medicinal properties of kola in fatigue have hitherto been ascribed. M. Bourquelot prepared an extract from fresh kola nuts which had been plunged into boiling alcohol to destroy the oxydase. This extract differed suggests certain interesting inquiries. We are led to ask, for instance, what was the principal cause of death in the eighteenth century, the age when Englishmen drank more deeply than at any time before or since? Surely in that age, if in no other, a large proportion of the male population "died of drink," and cirrhosis of the liver must have been very common. It is noticeable that biography throws very little light on these subjects. We read of famous men of letters who indulged in great drinking bouts and suffered, as did Dr. Johnson, from dropsical complaints. We read much of the tortures caused by calculi and gout and of deaths from dropsy. But we hear nothing of death attributable to drink as such. Again, the bills of mortality leave us much in the dark. In the oldest bills of the time of Charles II. we find dropsy figuring next to consumption as a cause of death, the latter invariably heading the quaint list of diseases from which our ancestors died. Now this dropsy, which had carried off on an average from 20 to 30 out of every 400 of the population buried, may have been chiefly of hepatic origin. We are inclined to think that it was. The record of necropsies before the nineteenth century is most unsatisfactory. Laennec was one of the first to give an account of liver diseases, but before his time the appearance of the liver after death is a matter of the most fantastic and perfunctory description.

---

[1] THE LANCET, May 26th, 1906, p. 1532.

APPENDICECTOMY AN HOUR AFTER PARTURITION.

OPERATION for appendicitis has now been frequently performed during pregnancy but we do not know of any case like the following in which it was done just after labour. In the *Intercolonial Medical Journal of Australasia* for May Mr. J. W. Dunbar Hooper has reported the case of a woman, aged 32 years, who was expecting her fourth confinement on Feb. 16th, 1906. On Feb. 6th he saw her at 9.30 A.M. She was quite well but as she was anxious he performed abdominal palpation and ascertained that the child was in the left occipito-anterior position. He examined both iliac fossæ without finding any pain. The patient took a dose of castor oil which acted satisfactorily but was followed twice by vomiting. At 3 P.M. she was in considerable pain and was certain that labour had begun but the nurse was equally convinced that the pain was unlike that of labour. At 4 P.M. Mr. Hooper saw the patient and was struck by her altered appearance. She was lying on the left side with the right knee drawn up, the face pale grey, and the expression anxious. The pulse was 120 and the temperature was 99°F. There were slight headache and distinct nausea. The patient was afraid to move because the slightest movement of the right leg produced great pain in the lower abdomen. McBurney's point was very tender. There were no signs of labour, even on vaginal examination. Acute appendicitis was diagnosed. A consultation with two other practitioners was held and it was decided to operate without waiting for the onset of labour or of suppuration. However, she was left in charge of the nurse for the night with orders to report immediately any change. On the following morning the tenderness at McBurney's point persisted and some swelling was found there. She was removed to hospital for operation but on the way labour began. She arrived at 11.30 A.M. From 1 until 3.30 P.M., when the child was born, she was kept under chloroform. At 4 P.M. Mr. Hooper slowly expressed the placenta. A distinct but not very tender mass could be felt in the position of the appendix. At 4.15 laparotomy was performed. The appendix was found adherent to the omentum and was removed. It was very large and of a greenish-grey colour. It would have ruptured if not gently handled. The patient rallied well and except for a mild attack of phlebitis recovery was uninterrupted. Dr. J. F. Mackeddie, pathologist to the Alfred Hospital, Melbourne, reported that the appendix was twisted, enormously swollen, dusky, and lustreless. In parts its wall was thickened almost to obliteration of the lumen; in other parts the dilated canal was on the point of rupture through the wall thinned almost like tissue paper. Microscopically the contents were grumous débris containing pus organisms and colon-like bacilli. Sections of the thickened wall showed chronic inflammatory changes on which acute had supervened.

A USEFUL PUBLICATION BY THE BOARD OF AGRICULTURE AND FISHERIES.[1]

THE Board of Agriculture and Fisheries has undertaken the publication of a geological survey of the soils and subsoils of London from a sanitary point of view, and we congratulate the originator upon a useful idea. The memoir deals exhaustively with the soils and the subsoils of London and its environs with reference to sites for houses. Questions of water-supply, of ground-water, and of drainage are also dealt with in their sanitary aspects. The geology of the district is described according to the nature of the subsoil, whether clayey, sandy, gravelly, or chalky. A small colour-printed map accompanies the letter-press and the memoir is further illustrated by 22 sections and drawings. The memoir is a re-issue of a small work written by Mr. Horace B. Woodward, F.R.S., additions having been made to the text, especially in the chapters dealing with water-supply and drainage; and copies may be obtained from any agents for the sale of ordnance survey maps, or directly, or through any bookseller, from the Ordnance Survey Office, Southampton, price 1*s*. 6*d*. We are constantly asked where trustworthy advice can be obtained upon the points dealt with in this small book. The public is now very much alive to the advantages of residing in a house upon a suitable foundation and medical men are more than occasionally invited to give their opinion as to the district in which a house should be hired or bought, where the head of the family must remain in London for reasons of business, and where his particular diathesis forbids him to do so save in the most favourable environment. Mr. Woodward's manual supplies suggestions for authoritative answers to all questions of this sort.

FOURTEENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

THE Fourteenth International Congress of Hygiene and Demography will take place from Sept. 23rd to 29th, 1907, in Berlin. The committee of organisation under the presidency of Mr. Bumm, President of the Imperial Board of Health, has forwarded the preparatory work of the Congress to such a degree that the invitations will be shortly issued. The work of the Congress, which will probably take place in the locality of the Reichstag, is divided into the following sections:—Section 1: Hygienic Microbiology and Parasitology. Section 2: Dietetic Hygiene, Hygienic Physiology. Section 3: Hygiene of Childhood and Schools. Section 4: Professional Hygiene and Care of the Working Classes. Section 5: Combating Infectious Diseases and Care of the Sick. Section 6A: Hygiene of Dwellings and Townships. Section 6B: Hygiene of Traffic. Section 7: Military, Colonial, and Naval Hygiene. Section 8: Demography. The direction of a scientific exposition associated with the Congress has been undertaken by Professor Geheimer Medizinalrat Dr.

---

[1] Memoirs of the Geological Survey, England and Wales: Soils and Subsoils from a Sanitary Point of View, with especial reference to London and its neighbourhood. By Horace B. Woodward, F.R.S. London: Printed for *His Majesty's Stationery Office* by Wyman and Sons, Limited, Fetter lane, E.C. And to be purchased, either directly or through any bookseller, from Edward Stanford, 12, 13, and 14, Long Acre, London, or John Menzies and Co., Rose street, Edinburgh, or Hodges, Figgis, and Co., Limited, 104, Grafton-street, Dublin. 1906. Price 1*s*. 6*d*.

preservative is found. Also it is suggested that when the presence of a preservative is declared the condition of such preserved milk should be carefully examined. As regards formalin and boron preservatives the Board is advised that the presence in milk of formalin to an amount which is ascertained by examination within three days of collecting the sample to exceed 1 part in 40,000 raises a strong presumption that the article has been rendered injurious to health and that the purchaser has been prejudiced in the sense conveyed in Section 6 of the Sale of Food and Drugs Act. A similar presumption is raised where boron preservatives are found in milk to an amount exceeding 57 parts of boric acid per 100,000 parts of milk. The despatch of this circular to the authorities administering the Sale of Food and Drugs Act looks as though the Local Government Board at last means to codify the recommendations of the Departmental Committee on Preservatives and Colouring Matter in Food which reported so long ago as 1901. We have long urged for an official recognition of the findings of this committee.

DE SENECTUTE IN PUBLIC OFFICES.

A LIVELY and interesting discussion in the board room of the Islington guardians is reported on the subject of the retirement of officers of the board on or after the attainment of the age of 65 years. The particular case which gave rise to the discussion was that of Dr. James Greenwood who, according to the report of the finance committee, must be 73 years old at least. The committee, especially having regard to a probable rearrangement of districts, thinks that the time is fit for Dr. Greenwood's retirement and recommended the board to pass a resolution to this effect and to forward it to the Local Government Board. There is, of course, much to be said for retirement from public offices on the score of age. But the finance committee found itself in a minority of two on the proposal and even these two found themselves hoist with their own petard. Notice was given by Mr. Malins, one of the majority, that at the next meeting he would propose that the *two guardians* who constituted the minority should be called on to resign on account of their age. Mr. Lambert, one of these guardians, is well known as a most competent and active member of the board, of the Metropolitan Asylums Board, and of the borough council. We sincerely hope that his public usefulness will not be cut short by any such action. We express no opinion on the merits of the argument beyond saying that the case for the medical officer was well put, especially by the vigorous chairman of the board, Mr. G. S. Elliott, who shrewdly said that many men of 70 were better men than others at 40; that there had not been a single complaint against Dr. Greenwood; and that he was much respected by the poor in his district. It would seem that Dr. Greenwood is one of those exceptional men who belie their age and that he still displays an agility and activity which have always characterised him in his long Poor-law service of over 50 years. Such qualities are always interesting and may justify recognition in an age which is trying to extend the health and the life of the race.

THE ACCIDENT TO THE PLYMOUTH BOAT EXPRESS.

THE inquest on the bodies of those persons who lost their lives in the accident to the Plymouth boat express on July 1st was concluded at Salisbury by the city coroner, Mr. Buchanan Smith, on July 16th. Evidence was given that the train which according to the London and South Western Railway Company's regulations should have travelled round the curve near Salisbury station at a speed not exceeding 30 miles an hour actually did so at a speed of from 60 to 70 miles per hour. The jury returned a verdict to the effect that the deceased lost their lives owing to the derailment of the train, that the derailment was caused by the excessive speed at which the train was travelling, and that this was contrary to the company's regulations. They added a rider to the effect that every driver of a train not stopping at Salisbury ought to have his attention specially called before starting to the regulations affecting his journey and that this was not done in this case. The coroner said that the recommendation of the jury would be forwarded to the Board of Trade. Quickness of intercommunication is no doubt a desirable thing but it can be purchased at too high a cost. British railways are, it must be admitted, singularly free from accidents to trains but in many instances it is the public who are primarily to blame for delays and the possibilities of accident. In many of the companies serving the suburbs the amount of traffic has increased to a much greater extent than the roadways are really able to bear. Hence an increased number of trains, most of which are unpunctual, and unpunctuality always means the possibility of accident. Yet the public demand frequent trains and grumble if these are not provided. We may add that it is the same desire for rapidity of intercommunication which has made London streets an experimental ground for machines which are absolutely unfitted for the purposes to which they are daily applied.

THE Department of Public Health of Queensland in a bulletin dated June 9th reports that the last case of plague which occurred in Queensland was notified on May 16th of the current year. As regards the Cape Colony the medical officer of health of the colony reports that for the week ending June 23rd no case of plague in man or other animal occurred except at East London, where 2 plague-infected mice were found. As regards the Mauritius, a telegram from the Acting Governor received at the Colonial Office on July 14th states that for the week ending July 13th there were 1 case of plague and 1 death from the disease. As regards Hong-Kong, a telegram from the Governor received at the Colonial Office on July 16th states that for the week ending July 14th there were 14 cases of plague and 17 deaths from the disease.

THE King has given to the undermentioned gentlemen His Majesty's Royal licence and authority to accept and wear the insignia of the *Order of El Aliyeh* which has been conferred upon them by His Highness the Sultan of Zanzibar in recognition of valuable services rendered by them to His Highness, viz. :—Mr. Alfred Henry Spurrier, L.R.C.P. Lond. (second class); Mr. George Allardice MacDonald, M.B., C.M. Edin., and Mr. Archibald Donald MacKinnon, C.M.G., M.D. Aberd. (third class); and Mr. Henry Deedes Nutt Mackenzie, M.D. Edin. (fourth class).

A CONVERSAZIONE and dance will be given by the Irish Medical Schools' and Graduates' Association at the Hotel Great Central on Thursday, July 26th, at 9 P.M., to meet the council and representatives of the British Medical Association. Members of the Irish Medical Schools' and Graduates' Association can obtain tickets from Mr. E. Canny Ryall, 85, Harley-street, W.

AT a recent general meeting of the members of the Incorporated Institute of Hygiene Sir William H. Broadbent, Bart., was elected President and Sir William H. Bennett, Surgeon-General J. Cleghorn, Sir Alfred Cooper, Mr. A. W. Mayo Robson, and Professor G. Sims Woodhead were elected as Vice-Presidents of the Institute.

THE council and headmaster of Epsom College are issuing invitations for the annual prize distribution to be held on Founder's Day, July 28th, between 2.30 and 7.30. There will be choral evensong at 2.45 in the college chapel and the distribution of prizes will take place at 3.30 in the big schoolroom.

from the ordinary extract of kola in containing only traces of free caffeine, though from 8 to 9 per cent. of caffeine was present in the form of a complex chemical compound, probably the glucoside kolanin. The extract possessed medicinal properties equal in intensity to those of fresh nuts and afforded an excellent illustration of the value of employing drugs in the fresh state when possible and of preventing those changes which are induced by the presence of oxydases. M. Perrot suggests that further investigations on the same lines may lead to the discovery of better methods for the manufacture of galenical preparations which shall be wholly representative of the drugs from which they are made.

THE MEDICAL INSPECTION OF CHILDREN ATTENDING ELEMENTARY SCHOOLS.

On July 16th Mr. A. Birrell, President of the Board of Education, received a deputation from the British Medical Association and from the Manchester and Salford Sanitary Association. Mr. Tennant, M.P., who introduced the deputation, said that the members thereof were anxious that the clauses in the Education Bill now under discussion concerning medical inspection should be made compulsory instead of voluntary. Sir Victor Horsley and Sir William H. Broadbent both spoke in support of the aims of the deputation. Mr. Birrell adopted the stereotyped form of reply upon such occasions. He had every sympathy with the desires of the deputation but he could not see his way to grant their requests. There was the spectre of the rates and he had received a deputation from ratepayers who did not share the views of the deputation which he was then receiving. All the same, every pressure would be put by the Board of Education upon local authorities to make such arrangements as they could. We have upon various occasions, notably in our issue of Feb. 24th, p. 536, and in that of April 21st, p. 1123, given the opinion that medical inspection is most desirable. As we said in the article referred to in our issue of Feb. 24th, the State compels parents to send their children to school, or at least to have them educated, and this being so it is surely the duty of the State to find some way in which children attending school shall be prevented from being failures on account of their own ill-health or physical deficiencies or a source of danger to their fellows. In the course of the debate on the Bill during the same day in the House of Commons Mr. Tennant moved an amendment to one of the clauses to secure compulsory medical inspection of the children. Mr. Birrell said that he was in the hands of the House. He was willing to put down for the report stage an amendment to the following effect: "It shall be the duty of every local authority to provide for the medical inspection of every child on its application for admission to a public elementary school and on such other occasion as the Board of Education may direct or the local education authority may think fit." The matter will therefore be further discussed during the report stage of the Bill and we hope that in addition the question of the payment of the inspecting medical men will come up. Governments have a way of ordering people to send for medical men, without making any provision for the payment of the medical man sought for. An example in point is the Midwives Registration Act.

MICROCEPHALICS AT THE HIPPODROME.

From time to time the enterprising management of the Hippodrome includes in its programme items which have an interest not only for the morbidly curious but also for the genuine anthropologist. Last year it secured a group of pygmies from Central Africa—a race never before seen in England; they became an attraction for "society" and the subject of an elaborate memoir (not yet published) by a committee of the Anthropological Institute of Great Britain and Ireland. Some months ago a Russian gentleman took his place in the programme; he was over eight feet in height; he was huge in every respect excepting the cranial or brain-containing part of his skull which was of very ordinary proportions. His face was massive and very placid; his voice was sepulchral, but he was so obstinate and suspicious in nature that he absolutely refused to be examined or measured. At the present time three very remarkable individuals are being shown. They are supposed to be representatives of a native race of America (Mexico ?) which is now almost extinct. No history can be obtained beyond the fact that the German gentleman who now guides their destinies discovered them in Germany whither they had been brought from America by a citizen of the United States. They provide, therefore, a very interesting problem for an enterprising physical anthropologist. The cranial parts of their heads are uncommonly small; the determination of the exact size of their brains is a matter for Professor Karl Pearson, but from measurements made of their heads their brain weights may be estimated to range between 500 and 600 grammes, considerably less than half that of the average individual. Their heads have the typical microcephalic form. Their skins are rather deeply pigmented—a brown tint, but the pigment is peculiarly superficial in deposit and apparently not permanent. The sex in each case is probably female but the breasts are not developed; the palates are narrow and vaulted; the state of their dentitions shows them to be under 20 years of age. The colour of the iris scarcely matches the complexion of the skin and indicates a very close relationship with one of the lighter-haired European races. The hair is tied in a bush-like mass on the crown of the head, thus emphasising the peculiar smallness of the skull; the coiffure is one which we do not remember to have seen before in a native race. Their manners are polite and easy; they shake hands in the approved European fashion; in fact, it must be concluded that their native manners have been entirely replaced during their short stay in Germany. They speak no language and the only words which they seem to understand belong to the German form of speech. As will be seen from the brief account just given, these "representatives of an almost extinct native race" are of interest not only to students of anthropology but also to those of human nature.

PRESERVATIVES IN MILK.

We are glad to see that the Local Government Board is drawing the attention of the authorities who are responsible for the administration of the Sale of Food and Drugs Acts to the fact that the use of preservatives in milk is not a sine *quâ non* to the trade. The Board, in a circular recently issued, states that in certain boroughs in London and elsewhere in which samples of milk are systematically tested for preservatives, the presence of substances at any time of the year has been found to be exceptional and there is evidence to show that a very large number of milk vendors conduct their business without the use of antiseptics, even in those instances in which the milk comes long distances by rail. Proceedings instituted against vendors of milk containing preservatives have usually been taken under Section 6 of the Sale of Food and Drugs Act. Conviction has followed, it being held that when the purchaser who asks for milk is supplied with milk plus a preservative he does not receive an article of the nature, substance, and quality demanded and is prejudiced thereby. The Board suggests that analysts should record in their quarterly reports the number of samples of milk which have been examined with the view of ascertaining the presence of preservatives and should report at once to the council concerned the facts as to samples which proved on analysis to contain an added preservative. It is further suggested that proceedings should be taken in all cases where such a isappeared in five hours, and even 11·2 in a lake water, ar in excess of its requirements, had been resolved into hlorides and oxygen after a few days; in fact, the rapidity with which the hypochlorites broke up somewhat militated against their action. The resultant effect on London water after treatment with 0·44 part per 1,000,000 of "available chlorine" was a reduction of the oxygen consumed and an increase of the chlorides from 2·1 to 2·4 per 100,000.

International Notification of Infectious Diseases.

Dr. E. WALFORD (Cardiff) read a paper in which he dwelt on the futility of the existing practice of granting clean bills of health by our Consuls at foreign ports to homeward-bound vessels and the urgent need for an international organisation or bureau for the collection and circulation of information as to the existence of such diseases in ports in every land. At the Sanitary Conference held at Paris in 1903 the proposal, first made at the Vienna Congress in 1874, was formulated and strongly pressed by M. Barrère, who very properly insisted that it should be strictly international and wherever located, whether as he naturally desired at Paris or elsewhere, the local government should exercise no controlling influence over it. The British delegates, for reasons that Dr. Walford could not understand, had opposed it, maintaining that their Government had already all the information that they required or could expect to obtain by means of such an office, but facts coming under the almost daily observation of our port officers showed that such was far from being the case. The only valid objection was the loss and annoyance that might be inflicted by the authorities of countries which, like Spain, adhered to antiquated beliefs and practices by refusing admission to vessels coming from, say, Liverpool or Hamburg simply because the presence of a few cases of small-pox had been reported as existing in those towns, though instances of such hardship were not unknown at present, and official information of the presence of disease in any port would be a better ground than that obtained from newspaper paragraphs for the guidance of the health officers of other ports in the inspection of vessels coming from the infected port and therefore liable to have infection on board. Medical inspection of shipping on arrival was far from satisfactory; it was compulsory in respect of cholera, plague, and yellow fever only and in the smaller ports could not be said to exist. Many cases of disease, especially ambulant small-pox, were concealed or ignored, partly through the ignorance and want of diagnostic power of the masters and partly through wilful misapprehension of their responsibility. Deaths on the voyage were misdescribed or not reported and legal technicalities aided the deception. A ship arrived from Antwerp with a case of small-pox; she had a clean bill from the Consul and the captain declared that no illness had occurred *on the voyage*, which was technically correct, since she was a tramp whose voyage ended at Antwerp, whence she returned in ballast, the patient sickening after leaving that port. Sometimes the concealment admitted of no extenuation, as when a steamer having had several cases of small-pox on board in the course of her voyage from the East Indies landed five of them at a continental port where they were sent to the hospital and proceeded homewards with a clean bill of health endorsed by the British Consul. Fortunately, Dr. Walford had had unofficial information of her history and disregarding the clean bill he inspected the crew, with the result of finding two more cases, one convalescent but still infectious and the other in an early stage of the eruption. The Registrar-General, as Dr. Walford observed, did report certain outbreaks of infectious diseases in foreign countries, but the nearest approach to a universal notification is, we believe, to be found in the weekly bulletins of the German Imperial Board of Health in which the occurrence of outbreaks or the continued presence of any of the principal infectious diseases in the more important seaports in every part of the world are reported week by week, presumably from information afforded by the consular service.

SECTION OF CHEMISTRY, PHYSIOLOGY, AND BIOLOGY.

The Dust Nuisance.

Dr. PHILIP BOOBBYER (Nottingham) referred to the many evil results of dusty occupations and especially to the dust nuisance caused by motor vehicles on dusty roads. To mitigate this nuisance streets ought to be paved, he said, with smooth and cleanable material, the sweeping of dust from houses and shops into the street should be forbidden, and motor-cars in urban districts should not run at a higher speed than ten miles an hour.

Dr. A. BOSTOCK HILL (Warwickshire) protested against the horrible practice of putting refuse from the houses in the streets for collection. It was a practice as disgusting as it was dangerous to health. The motor had accentuated the dust nuisance.

Professor H. R. KENWOOD (London) admitted that the dust nuisance was a very great one, but it afflicted motorists more than anyone else. The remedy was improved scavenging and watering and better road makers.

Dr. S. RIDEAL (London) considered that the dirt nuisance would be greatly mitigated if the hedges were cut down so as to give a free course for the dissemination of the dust over the fields.

Dr. BOOBBYER, in replying to the discussion, said they had a painful picture from motorists of their sufferings for their misdeeds. He objected to the public also suffering. He objected to having his front garden rendered uninhabitable on a Sunday afternoon by "road hogs" tearing along the road at 30 miles an hour.

CONFERENCE OF MEDICAL OFFICERS OF HEALTH.

The Milk-supply.

Dr. H. RENNEY (Sunderland) referred to the pressing need of licensing dairies, cowsheds, and milkshops. In the shops in the poorer parts of towns it was not uncommon to find a number of small shops in one street often quite close together, the proprietors of which sold from a quart to a gallon of milk per day. These shops were usually small grocers or general dealers, and on inspecting them one found the milk contained in an earthenware vessel without any covering standing on the counter. He had seen it kept in a dirty zinc pail. In close proximity to the milk were pickles, kippered herrings, onions, flour, coals, perhaps an open tin of so-called preserved meat, and even paraffin oil. The floor was dirty with a layer of dried mud from the street, the walls and ceiling were sadly in need of cleansing, and the place usually communicated with the living room, where the stock of bread was being baked, to be afterwards sold in the shop. He proposed that:—

> In consideration of the insanitary condition of the great majority of dairies, cowsheds, and milkshops which thereby renders the milk supplied, under such insanitary conditions, unfit for human consumption and dangerous to the public health this section is of the opinion that legislation is desirable to secure the licensing of all dairies, cowsheds, and milkshops in lieu of registration as at present; and this section recommends the council of the institute to bring the proposition under the notice of the proper authorities.

Professor KENWOOD seconded the motion and suggested that the licences should be issued annually, which was accepted.

Dr. T. EUSTACE HILL (Darlington) considered that the enforcement of regulations in small districts was intimately bound up with the question of security of tenure of the official. Any dairyman could drive a coach-and-four through the model regulations of the Local Government Board.

Dr. H. E. ARMSTRONG (Newcastle-on-Tyne) believed that nothing short of a combination of sanitary authorities would solve the troubles between milk-sellers and consumers.

The motion was unanimously adopted.

SECTION OF ENGINEERING AND ARCHITECTURE.

Water-supply.

Dr. E. F. WILLOUGHBY (London) read a paper on Rural Water Supplies and urged that the county council should be empowered to authorise, or to compel, the formation of water boards for the supply of combined districts devoid of the means of supplying themselves.

We hope to be able to notice the interesting health exhibition which was held in connexion with the congress in a forthcoming issue.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ELECTION OF PRESIDENT.

A QUARTERLY meeting of the Council was held on July 12th, Mr. JOHN TWEEDY, the President, being in the chair.

The PRESIDENT reported the result of the recent election

THE ROYAL SANITARY INSTITUTE.

The twenty-third Congress of the Royal Sanitary Institute was held at Bristol from July 9th to 14th. The inaugural address was delivered by the President, Sir Edward Fry.

Section of Sanitary Science and Preventive Medicine.

The President of this section, Sir William J. Collins, being unavoidably absent, the address was read for him by Dr. R. Shingleton Smith. The gist of the address will be found in The Lancet of July 14th, p. 106.

The Spread of Diphtheria.

Dr. F. T. Bond (Gloucestershire) read a paper on the Spread of Diphtheria, especially in rural districts, and the difficulties that the medical officer of health encountered in his efforts to suppress the outbreaks. Dismissing as absolutely imaginary the notion of any connexion between "drains and diphtheria," he traced the story of rural epidemics from the alighting of some bacillus in the requisite stage of specificity on the mucous membrane of the congested tonsils or fauces of some child in perhaps an elevated and sanitary locality and the spread of the infection from child to child in the school until the outbreak assumed the proportions of an epidemic, according to the number of scholars and overcrowding of the school. What, he asked, should then be done? Closure was a clumsy and ineffective procedure and should rarely be resorted to. He told how in two adjoining villages with a combined school population of 470, after a long succession of notifications extending over several months, he obtained swabs from the throats and noses of all, with the result that more or less characteristic bacilli were found in the throat only in 16 cases, in the nose in 149, and in both in 230, while only 83 gave negative results. The preponderance of nasal infection was thus well seen. His subsequent procedure, to some extent experimental, was to have the noses and throats of all the children sprayed twice daily with a 10 per cent. solution of carbolic acid, with the result that in the next six months there were only five cases, three of them being in one house. But what was notifiable diphtheria? This was easy to answer 40 years ago, but they knew now that they might have well-marked membrane without diphtheria and diphtheria with no membrane. Only by bacterioscopy could the question of diagnosis be decided and it was doubtful whether, and from whom, the medical officer of health could look for remuneration. If he could pronounce the child to be suffering from diphtheria, as he might in even slight cases showing abundant growths of Klebs-Löffler bacilli, the sanitary authority—i.e., the ratepayers—could be called on; but the wider questions, the inspection of an entire school and subsequent preventive sprayings ought to be defrayed by the Board of Education. Then as regards antitoxins. Legally they could supply them gratuitously only to patients in the hospital, and to no other persons save by a pious fiction, charging it to the expenses of the hospital. A board of guardians might supply it to paupers, indoor or outdoor, and to them only. But an urban council without a hospital could not supply antitoxin at all.

Dr. J. Fletcher, representing the Metropolitan Asylums Board, as Dr. Bond did a county mainly agricultural, repudiated, too, any connexion of diphtheria with sewer gases or insanitary conditions. In his paper he confined his attention to the form known as post-scarlatinal, of which in the years 1896–1901 inclusive the Board had had in its hospitals an attack-rate of 4·4 per cent. among 81,245 scarlet fever patients, though owing to the extending use of antitoxin the fatality-rate had sunk from 43·3 per cent. in 1892 to 2·5. By far the greater proportion of these cases arose from infection from persons who, though without any clinical symptoms, harboured the bacilli in their throats or noses, "carriers" as they were called. Members of the staff might act thus, indeed he knew one case of a nurse suffering from mild pharyngeal diphtheria infecting 16 scarlatinal convalescents, six of whom died. He gave very fully details of a series of cases of post-scarlatinal diphtheria at Ham Green Hospital whence he concluded that the bacilli, however introduced, lurked in the mucous membrane of the nares and fauces of scarlatinal patients in a dormant state, springing into activity when, as was often the case between the fourth and sixth week of convalescence, a rhinorrhœa set in and swabs taken then from the nose would give almost pure cultures of Löffler's bacillus. On one occasion several patients had been admitted suffering from a certain amount of nasal catarrh but no notice was taken of the fact until the slow progress which they were making led to an examination of their nasal mucous, when out of 29 eleven showed Löffler's and six Hoffmann's bacilli, 12 being negative. These last were removed to the convalescent wards where one after another developed clinical symptoms of diphtheria and communicated it to others previously admitted until prophylactic doses of 2000 units of antitoxin promptly arrested the further progress of the disease.

Dr. Symes (Bristol), after ten years' experience of bacterial examination, attached little value to it. On one occasion 50 per cent. of the children attending a skin hospital showed diphtheria bacilli in their noses or throats and he would point out that they could never sterilise throats. In one place all cases of bacterial diphtheria were sent to hospital where nearly every one developed clinical diphtheria. It was well worth consideration that post-scarlatinal diphtheria was practically confined to hospitals and was almost unknown in private practice.

There followed a short passage of arms between Dr. Symes and Mr. Herbert Jones, who thought that it was superfluous to look for bacteria in the presence of clinical symptoms, while Dr. Symes believing that the bacteria without symptoms were harmless now employed examination in clinical cases only with a view to verify their specific character.

Sir Charles A. Cameron (Dublin) held that sore-throats were certainly connected with bad drains and might predispose to diphtheria. In Dublin with improved sewerage sore-throats had become much less prevalent, but the diminution of diphtheria was less marked in consequence of the overcrowding of the population, 37 per cent. of whom lived in single rooms, though fairly large ones.

Dr. E. M. Smith (York) raised an earnest protest against the growing belief in the harmlessness of sewer air and bad drains, against which there was a mass of evidence that could not be lightly ignored.

Prevention of the Growth of Algæ in Open Reservoirs.

Dr. S. Rideal, F.I.C. (London), read a paper on the Employment of Copper Sulphate and of Chlorine Evolved in the Electrolysis of Common Salt Solutions. The earliest experiments with the copper salt were made in America by Dr. G. T. Moore of the United States Agricultural Department, who found that the various orders of algæ were destroyed by copper sulphate in dilutions of from 1 in 8,000,000 parts to 1 in 1,000,000, but up to last year its employment had not been sanctioned by the Board of Health of Massachusetts. Mr. Reid, engineer to the Gloucester waterworks, had used it in the proportion of 1 in 3,000,000 with most satisfactory results, a single application in early spring inhibiting the growth of the chara for the remainder of the season. For 24 hours after the addition of the sulphate the water gave off bubbles of a strongly fishy odour but was then bright and clear and after another 24 hours not a trace of copper was discoverable by the cyanide test, the metal having combined with the organic sediment, and the filters required far less cleaning than previously. The only objection was the popular prejudice against the employment of copper in any form in connexion with articles of food or drink and though in this case the danger was imaginary it provided an argument in favour of the substitution of the alternative of nascent chlorine. Chlorine evolved by the electrolysis of sea water or of solutions of common salt had proved very successful in the purification of sewage effluents and Dr. Rideal believed that it would be found equally applicable to potable waters. It was true that a special electrolytic plant was required but the Digby hypochlorite apparatus could be installed at a cost not exceeding £100 and the requisite power was available wherever pumping operations were carried on, while the material, common salt, was considerably cheaper than copper sulphate at £28 per ton, though this at 1 part per 1,000,000 worked out at no more than 2*s.* 6*d.* for each 1,000,000 gallons of water treated. Chlorine was most effective with algæ of the convervoid type; dermids and diatoms were more resistant and entomostraca were not killed even by the largest quantities required by the algæ or permissible in potable waters. The "available chlorine" consumed by these rarely exceeded 0·5 part per 1,000,000, and by lake waters 1 or 1·2, but these quantities “open grate” in the sense intended or as suitable where an open fire is required.

In the matter of smoke production the results afforded by the anthracite stoves are remarkable in comparison with those of stoves consuming bituminous coal, the smoke produced by the former kind being practically *nil* and imperceptible to ordinary observation.

If further efforts should succeed in securing with these results increased heat production combined with economy in fuel consumption a valuable achievement will have been accomplished, and, in the opinion of the committee, the problem is well worthy the attention of inventors and manufacturers.

The following are descriptions of the grates tested arranged in alphabetical order according to the name of the manufacturer or patentee. The descriptions are supplied by the manufacturers but their inclusion in this report is not to be taken as implying confirmation by the examiners of statements therein contained. The results stated at the foot of each description have been added by the examiners and indicate the daily average consumption of coal, the average rise of temperature, and the emission of smoke.

The Coalbrookdale Company.—The “Kyrle” open fireplace.—This fireplace is constructed to burn anthracite. The fire space is lined entirely with fire brick, the bottom being solid. The draught is through the front bars and through the narrow horizontal opening at the bottom of the fire-brick back into the back flue. Passing upwards, the external air is drawn in over the top of the fire, through another narrow slit between the back brick and a deflector brick fixed immediately above it at an angle. There are no extraordinary flues, dampers, valves, or loose doors to get out of order.

Coal, 39·1 lb. Temperature, 5·4° F. Smoke, 0·15.

The Downdraught Fireplace Company.—The “Tiffin” interior.—A downdraught flue is carried up from the bottom of the fire on either side behind the usual firebrick cheeks. These flues are made to converge to a common centre immediately above the usual adjustable canopy and thence a single flue is carried round the oven or hot chamber, finally debouching behind the same into the chimney. On the under side of the hot chamber, where the converging flues meet, a sliding soot-door is fitted, reached for cleaning purposes by removing the adjustable canopy in the ordinary way. The downdraught flue is regulated by a damper and this is actuated by a rod passing through the front of the stove. When the damper is drawn an induced draught creates a downward suction through the fire by which the smoke and heated gases are consumed.

Coal, 36·13 lb. Temperature, 4·7° F Smoke, 0·09.

Messrs. Eames and Keys.—Cleaver's patent “cascade” fire.—An open fire for burning anthracite coal broken into small fragments; it has an automatic coal-supply whereby the fuel is replenished as it is consumed, requiring no attention or stoking. By means of a damper operated by a small handle the heat may be regulated at will or the fire extinguished.

Coal, 24·27 lb. Temperature, 3·1° F. Smoke, 0·04.

Messrs. Pither's Stove.—The stove is composed of an inner and outer casing of cast malleable iron, the area in the top part being a reservoir for coal, from which a funnel-shaped feed leads to the top of the fire, reducing the depth of fire to two and a half inches. The bars are louvre turned inwards to prevent coal falling out. The bottom is solid and arranged to tip when it is required to renew the fire.

Coal, 27·53 lb. Temperature, 8·2° F. Smoke, 0·09.

The Sinclair Iron Company.—The “Roseneath” open grate.—Combustion is regulated by a sliding shutter adjustable to suit the draught of chimneys and the temperature of the room.

Coal, 35·43 lb. Temperature, 2·1° F. Smoke, 0·02.

Table Showing the Results of Tests on Five Grates burning Anthracite Coal.

Names of firms.	Room.	Chimney.	Amount of coal (– cinders + half wood) in pounds.	Ashes in pounds.	Stoking.	Temperatures.				Smoke.
						[*] I.	[*] II.	Difference.	[*] III.

Looking Back.

FROM

THE LANCET, *SATURDAY*, July 19th, 1828.

IDIOSYNCRASIES.

THAT curious, sympathetic wonder-working person, Sir Kenelm Digby, is, perhaps, the greatest detailer of singular fancies relating to antipathies and sympathies. He narrates the dire effects of flowers upon certain people, even to fainting and dying. So obnoxious was a rose to the Lady Heneage, that she had her cheeks blistered, says Sir Kenelm, by laying a rose upon it while she was asleep. It is even stated that Cardinal Caraffa, and a noble Venetian, one of the Barbarage, were confined to their palaces, during the rose season, for fear of their lives.[*] Johannes e Querceto, a Parisian, and Secretary to Francis I., King of France, was forced to stop his nostrils with bread when there were any *apples* at table; and so offensive was the smell to him, that if an apple had been held near him he would fall a bleeding. (*Schenck. Obs. Med.*)—I saw a noble countess, says Horstius, who tasted of some udder of beef, and had her lips suddenly swelled thereby; observing that I took notice of it, told me that she had no dislike to that kind of dish, but as often as she did eat of it she was troubled in this manner, the cause of which she was utterly ignorant of. Bruverinus knew a girl, 16 years of age, who, up to that time, had lived entirely on milk, and could not bear the smell of bread; the smallest particle of which she would discover by the smell. An antipathy to pork is very common. Shenckius tells us of one who would immediately swoon as often as a pig was set before him, even though it be inclosed in paste; he falls down as one that is dead, nor doth he return to himself till the pig is taken away from the table. Marshal Albert fainted away whenever he saw the head of a boar.

The foregoing extracts are taken from a very ingenious and humorous paper in the last number of Brande's Quarterly Journal, by Mr. Wadd, entitled, “Comments on Corpulency.” To the unaccountable anomalies which he has mentioned, many others might be added from various authorities, and not a few from our own personal observation. In fact, there is not a single function of the body which does not frequently afford an instance of these irregularities. The feel of velvet produces nausea and syncope with some persons: of this the family of the writer presents a remarkable case. Gaubius speaks of a man who could not withstand the emanations from a female; and Rousseau mentions a young man who was afflicted with retention of urine, on hearing the bag-pipe. Mr. Wadd has alluded to a case, in which the odour of ipecacuanha produced violent effects; nausea and sickness. We have a highly respected friend of extensive practice in the country, who, if he chance to enter a room where ipecacuanha has been used, is suddenly seized with violent sneezing, watering from the eyes, and coughing. A short time since we were in attendance upon a lady, who is invariably seized with the most violent itching and tingling in the skin, if the smallest quantity of opium be administered.

---

[*] Not long since the English newspapers announced that a certain noble duke was confined to his room with the *hay-fever*, produced by the smell of new-made hay! “*Die of a rose, in aromatic pain,*” says *Pope.*

MEDICINE AND THE LAW.

Notification in Case of Measles.

Is measles a dangerous infectious disorder within the meaning of Sections 120 to 130 of the Public Health Act, 1875? Although the disease is not included in the list mentioned in the Infectious Diseases (Notification) Act, 1889, there seems no reason why it should not be so considered, if it is in fact a dangerous infectious disorder. Section 6 of the Act of 1889 enacts that in this Act the expression “infectious diseases to which this Act applies” means any of the following diseases: namely, small-pox, cholera, diphtheria, membranous croup, erysipelas, the of members of the Council, as published in THE LANCET of July 14th, and Mr. Henry Morris, Mr. F. Richardson Cross, and Mr. George Arthur Wright were introduced; they made declarations in the form of the oath prescribed by the charter of 1800 and took their seats as members of the Council.

On the recommendation of the Museum Committee it was resolved to print vol. iii. of the second edition of the catalogue of the physiological series of Comparative Anatomy.

A report was received from the Board of Examiners in dental surgery recommending alterations in the regulations for the Licence. The consideration of the report was postponed to the next meeting of the Council.

The PRESIDENT reported that after the election of members of the Council on July 5th the Fellows' subscription dinner was held in the library and that 65 Fellows were present.

A letter was read from the PRESIDENT of the Pharmaceutical Society thanking the Council for the practical sympathy extended to the society in connexion with the Poisons and Pharmacy Bill.

A letter was read from Mr. JOHN LANGTON expressing appreciation of the kind message sent to him by the Council on the expiration of his official connexion with the College.

Mr J. WARD COUSINS moved and Mr. RICKMAN J. GODLEE seconded:—

That in the opinion of the Council of the Royal College of Surgeons of England it is essential for the efficient working of the Midwives Act, that adequate provision be made to secure just remuneration for professional services rendered by medical men when called into attendance by midwives practising under the Act.

The motion was carried.

Mr. HENRY MORRIS was elected President and Mr. EDMUND OWEN and Mr. GODLEE were appointed Vice-Presidents.

The following professors and lecturers were appointed for the ensuing Collegiate year. Hunterian professors: William Sampson Handley, John William Thomson Walker, John Howell Evans, William Wright, and Cecil Fowler Beadle. Arris and Gale lecturers: John Faulkner Dobson and Bertram Louis Abrahams. Erasmus Wilson lecturers: Willmott Henderson Evans, Reginald Cheyne Elmslie, and Kenneth Weldon Goadby.

The next meeting of the Council will be held on July 26th.

REPORT OF TESTS OF GRATES SUBMITTED FOR THE CONSUMPTION OF ANTHRACITE COAL.

[THIS REPORT IS SUPPLIED BY THE COAL SMOKE ABATEMENT SOCIETY.]

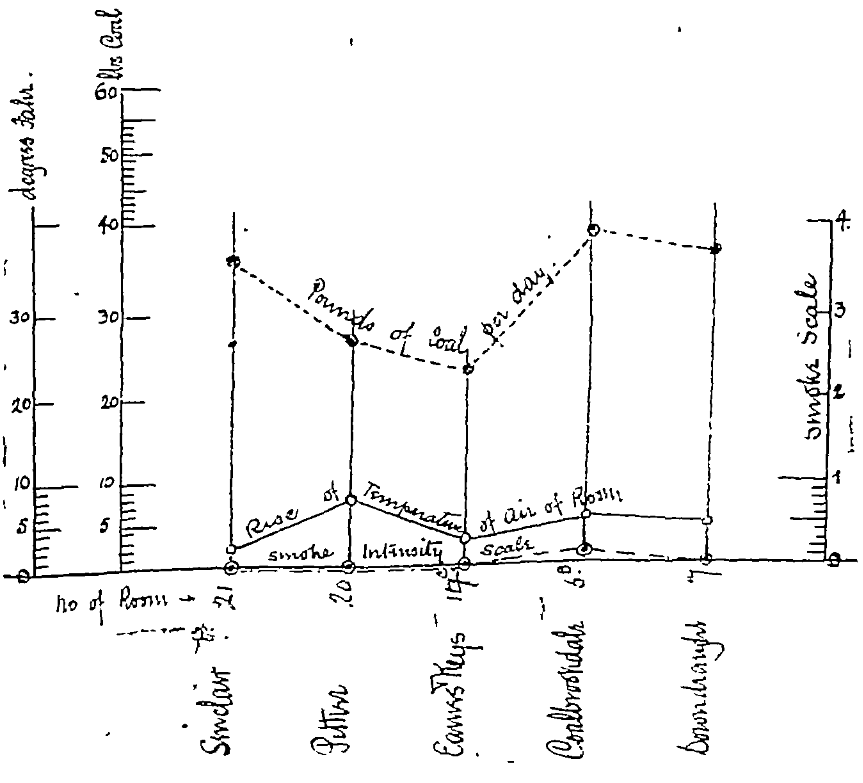
FIVE grates constructed for the consumption of anthracite coal were submitted for test—viz., by the Coalbrookdale Company, Limited, the Downdraught Company, Messrs. Eames and Keys, the Sinclair Company, Limited, and Messrs. Pither. These grates were tested on Jan. 2nd, 3rd, 4th, and 5th, 1906, by the same staff and under almost identical conditions and methods as described in our previous report published in THE LANCET of May 19th, 1906. The fires on one night were *allowed to burn themselves* out, which increased the amount of coal burnt as compared with the fires in previous tests.

The grate submitted by the Coalbrookdale Company for this test was identical with that tested with bituminous coal (Coalbrookdale Company).

All of these grates were open fireplaces with the exception of the grate submitted by Messrs. Pither, which, on the contrary, was almost closed, except for a small opening (1 ft. 1 in. × 6½ in.) in the lower portion of the front. The four other grates were entirely open.

The fires were started with paper or chips, wood, and a small quantity of bituminous coal. The heat given off by the entirely open grates was in every case small in proportion to the amount of coal consumed. The greatest average temperature from these grates was from that of the Coalbrookdale Company, registering 5·4° F. above the temperature in the corridor, and incurring an average consumption of 39·1 pounds of coal daily.

Messrs. Pither's stove produced an average temperature of 8·2° F. above corridor temperature, with an average daily consumption of 27 53 pounds of coal. The examiners, however, consider that this stove cannot fairly be accepted as an



therefore be some increased risk of pollution on the growth of the town in that direction." Although the sewers and drains within a radius of a quarter of a mile of these wells have been, it is said, carefully constructed and are reported to be under careful supervision we can quite understand the misgivings of Dr. Richards upon the whole question, more particularly as it is upon these wells that Croydon is dependent for the bulk of its water-supply. Filtration of this supply would certainly seem to be indicated. Dr. Richards suggests consideration by the Local Government Board of the whole question but possibly that Board might take the view that the Royal Commission on Sewage Disposal has indicated a way out of the difficulty by the appointment of Rivers Boards, which boards should have control of sewage disposal and water-supply in their districts. During 1905 a nurse was admitted into the isolation hospital under the following circumstances. Her mistress who was suffering from Malta fever left Malta with the nurse on July 2nd, reaching London on July 10th. Shortly after arrival the mistress suffered from a relapse and on August 1st the nurse who had remained with her mistress was attacked with an illness resembling enteric fever. But as the symptoms were somewhat anomalous a specimen of her blood was examined to ascertain whether it would agglutinate a culture of micrococcus Melitensis and a positive result was obtained, the subsequent course of the case confirming the diagnosis of Malta fever. The case, as Dr. Richards observes, raises some interesting speculations. Reporting to the education authority on March 23rd, 1906, Dr. Richards states that at that time there were no less than 180 children excluded from school on account of ringworm and he sets forth various reasons as to why the council should undertake the treatment of this condition. He has also, in his capacity as medical officer to the education authority, obtained data as regards the physical condition of school children and for purposes of comparison he has examined the boys in the Grammar School and the girls in the High School. The whole report as regards schools shows what a large tax the work must make upon the time of a medical officer of health and it accentuates the importance of assistance being provided for that officer.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 76 of the largest English towns 8322 births and 3556 deaths were registered during the week ending July 14th. The annual rate of mortality in these towns, which had been 12·4 and 12·3 in the two preceding weeks, further declined last week to 11·7 per 1000, and was the lowest rate recorded in any week of the present year. During the past four weeks the death-rate in these towns has averaged 12·4 per 1000, while in London the average rate during the same period has been as low as 12·3 per 1000. The lowest death-rates last week in the 76 towns were 4·9 in Newport (Mon.), 5·6 in East Ham, 6·2 in Hastings, 6·8 in Grimsby, and 6·9 in Bournemouth; the highest rates were 17·2 in St. Helens and in Burnley, 19·8 in Huddersfield, and 20·3 in Rochdale. The 3556 deaths in the 76 towns last week were 165 below the numbers in the previous week, and included 351 that were attributed to the principal epidemic diseases, against 372 and 406 in the two preceding weeks. of these, 113 resulted from diarrhœa, 97 from measles, 59 from whooping-cough, 39 from diphtheria, 27 from "fever" (principally enteric), 25 from scarlet fever, and one from small-pox. The deaths from these principal epidemic diseases were equal to an annual rate of 1·2 per 1000 in the 76 towns and to 1·0 per 1000 in London. No death from any of these diseases was recorded last week in Rhondda, Southampton, Stockport, Walsall, or in 12 other smaller towns, while they caused death-rates exceeding 2·5 per 1000 in West Ham, Manchester, Burnley, Preston, Rotherham, and Middlesbrough. The highest death-rates from measles occurred in Manchester, Burnley, Huddersfield, and Halifax; from whooping-cough in Rotherham, Middlesbrough, and Sunderland; and from diarrhœa in West Ham, Norwich, Bootle, and Preston. The 39 fatal cases of diphtheria included nine in London, four in Liverpool, and three in Bristol; scarlet fever caused six deaths in London, four in Sheffield, and two each in Birmingham and Rotherham; while of the 27 deaths from "fever" four belonged to London, four to West Ham, and two to Oldham. The fatal case of small-pox was registered in Hull. The four cases of small-pox under treatment in the Metropolitan Asylums hospitals at the end of last week showed a further decline from recent weekly numbers, and no new case was admitted during the week. The number of scarlet fever patients under treatment in these hospitals and in the London Fever Hospital on Saturday, July 14th, was 2840, or 73 more than the number on the previous Saturday; 406 new cases were admitted during the week, against 366 and 377 in the two preceding weeks. The deaths in London referred to pneumonia and other diseases of the respiratory organs, which had continuously declined in the 12 preceding weeks from 399 to 118, were 119 last week, but were 17 below the corrected average for the corresponding week of the four years 1902–05. The causes of 33, or 0·9 per cent., of the deaths registered in the 76 towns were not certified either by a registered medical practitioner or by a coroner. In West Ham, Portsmouth, Bristol, Manchester, Salford, Bradford, Leeds, Sheffield, and in 42 other smaller towns the causes of all the deaths were duly certified; only one uncertified death was registered in London and in each of 21 other smaller towns; while there were two such cases in Sunderland and three each in Leicester, Liverpool, and Gateshead.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in eight of the principal Scotch towns, which had been 16·0, 14·5, and 15·3 per 1000 in the three preceding weeks, declined again to 14·3 per 1000 in the week ending July 14th, but was 2·6 per 1000 in excess of the rate in the 76 large English towns. The rates in the eight Scotch towns last week ranged from 10·2 in Paisley and 10·7 in Leith to 15·5 in Glasgow and in Dundee and 17·0 in Greenock. The 491 deaths in the eight towns showed a decrease of 33 from the number registered in the preceding week, and included 22 which were referred to diarrhœa, 17 to whooping-cough, 12 to measles, seven to "fever," three to diphtheria, two to scarlet fever, and not one to small-pox. In all, 63 deaths resulted from these principal epidemic diseases last week, against 59 and 50 in the two preceding weeks; they were equal to an annual rate of 1·8 per 1000, which was 0·6 above the average rate during the week from the same diseases in the 76 English towns. The 22 deaths attributed to diarrhœa in the Scotch towns showed a slight increase upon the numbers in the two preceding weeks and included 14 in Glasgow, four in Dundee, and three in Aberdeen. The fatal cases of whooping-cough, which had been nine and eight in the two previous weeks, rose last wek to 17, of which nine occurred in Glasgow, five in Aberdeen, and two in Leith. The 12 deaths from measles were slightly in excess of the numbers in the two preceding weeks, and included seven in Edinburgh and five in Glasgow. All the seven deaths from "fever," of which four were returned as cerebro-spinal fever, were recorded in Glasgow, as were also two of the three fatal cases of diphtheria. The deaths in the eight towns referred to diseases of the respiratory organs, including pneumonia, which had declined in the five preceding weeks from 95 to 52, rose again last week to 59, but were six below the number returned in the corresponding week of last year. The causes of 28, or 5·7 per cent., of the deaths registered in the eight towns last week were not certified, the proportion of uncertified deaths in the 76 large English towns during the same week being only 0·9 per cent.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 16·4 and 16·9 per 1000 in the two preceding weeks, further rose to 16·7 per 1000 during the week ending July 14th. During the past four weeks the death-rate has averaged 18·1 per 1000, the rates during the same period being 12·3 in London and 14·1 in Edinburgh. The 136 deaths of Dublin residents registered during the week under notice were 13 in excess of the number in the preceding week, and included 12 which were referred to the principal epidemic diseases, against three, five, and four in the three preceding weeks; of these, six resulted from whooping-cough, three from diarrhœa, two from "fever," and one from measles. These 12 deaths were equal to an annual rate of 1·7 per 1000, the death-rates last week from the principal epidemic diseases being 1·0 in London and disease known as scarlatina or scarlet fever, and the fevers known by any of the following names—typhus, typhoid, enteric, relapsing, continued, or puerperal—and includes, as respects any particular district, any infectious disease to which this Act has been applied by the local authority of the district in manner provided by this Act. Section 7 of the same Act enacts that the local authority of any district to which this Act extends may from time to time by a resolution passed at a meeting of such authority where the like special notice of the meeting and of the intention to propose the motion has been given, as is required in the case of a meeting held for adopting this Act, order that this Act shall apply in its district to any infectious disease other than a disease specifically mentioned in this Act.

The control of measles is a subject which has troubled many local authorities and the results of notification and other means have not always been such as to encourage them to spend much money on taking additional measures. The question is one of great importance, as statistics show that no less than 13,000 deaths occur every year in England and Wales from this disease. The disease is generally looked upon as one of the inevitable ailments of infancy and many mothers think that the sooner their children have it so much the better, for then it will be over and they will no longer be liable to catch it. It seems, however, that as children get older the fatal nature of the disease becomes less marked. It is during their second year that the disease proves most fatal to children, "whilst the incidence of the attack is highest during the third, fourth, and fifth years of life." Between 90 and 95 per cent. of the deaths are among children under five years of age. This may, however, be due to the fact that by the time children in this country attain the age of five years the great majority of them have already suffered from the disease. Deaths from measles occur almost wholly among poor people. Thus children of the richer classes are better looked after, the disease is noticed sooner, and a medical man is called in. The children are isolated and properly nursed, so that serious results less often ensue from the illness. Whether it is possible to check epidemics or not is doubtful, but at present it would seem that they occur in most districts every two or three years and there can be no reason why their frequency should not be reduced. The disease is undoubtedly an infectious one and is thus probably preventable. Notification is one of the remedies that is frequently suggested and it has been tried by several local authorities. As we have seen, measles is not one of the diseases mentioned in the Infectious Diseases (Notification) Act, but it can be included if the local authority desires and the Local Government Board approves. It is notifiable in about 60 towns in England and Wales but in nearly as many other towns it has been tried for a time and discontinued. The principal difficulty in the way of notification is due to the fact that in very many cases medical men are not called in, especially in the earlier stages, when it is believed that the disease is most infectious. Another objection is that the expense is considerable and it is impossible, for want of room, to isolate the patients. One reason alleged for the frequency of epidemics is the existence of infant schools. Many medical officers of health are of opinion that the attendance at school of young children under five years of age does far more harm than good. It is among such children that the epidemic spreads most rapidly and the fact that the age limit for school children has been reduced is given as one reason why the recent efforts to reduce the mortality from measles have proved so fruitless. There are over 600,000 children under the age of five years attending elementary schools. It is among these children that the greatest incidence of attack occurs and it is when under five that nearly all the deaths occur. If it is correct that fatalities are fewer after five years of age then every attempt should be made to prevent young children from contracting the disease. The closing of schools for children under five years of age would tend to produce this effect as it would prevent them from mixing together and so spreading contagion. The best remedy at present to minimise the effect of the disease is to teach the mothers how to treat their children when ill with measles and to induce them to keep their other children at home. This has proved very successful in rural districts but it is not such an easy matter in towns and in tenement houses as the children meet and play with one another. In some districts the schools are closed during epidemics, and in others not at all.

The Jury of Matrons.

In continuation of the note in THE LANCET of July 14th, p. 118, upon the case of the woman who after being sentenced to death for murder at the recent Bodmin summer assizes pleaded pregnancy some further historical points of interest are suggested. In the olden time the mere man and even the man of medicine were supposed to be very ignorant concerning the facts of pregnancy, which were deemed to be the province of matrons, or the facts of childbirth which were presided over by midwives; the aid of the surgeon was only sought in cases of difficult or of mismanaged labours. The frequency with which women condemned at the Old Bailey or at the assizes "pleaded their belly" in pre-nineteenth century times is seemingly very remarkable until it is remembered that the records refer to "the old hanging days" when to commit any felony was a capital offence. There can be no doubt that sisterly sympathy with the accused and antipathy to the awful sentence, whether immediately or remotely executed, influenced the actual verdict of the jury of matrons much more than did the physical signs which they found. It will be remembered that the poet Gay in his *Beggar's Opera*, published in 1727, makes Mr. Peachum say of one of his associates, "She pleads her belly at worst," in stay of execution and in hope of reprieve and commutation of the capital sentence. Among the contemporary records of criminal proceedings it is not very uncommon to read that the plea of pregnancy—for that was what it amounted to in reality—was made a second time when the condemned woman again appeared in court; the fact, of course, does not speak very highly either for the expedition of justice or for the morality of contemporary remand homes. The jury of matrons was abolished in Ireland by the Juries Procedure Act, 1876. In 1882 the Parliamentary Bills Committee of the British Medical Association made representations to the Crown against empanelling such juries.

Public Health and Poor Law.

LOCAL GOVERNMENT BOARD.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH.

County Borough of Croydon.—Dr. H. Meredith Richards reports that the Croydon Corporation Bill, 1905, has now become law. This measure confers upon the corporation certain extended facilities as regards drainage and it also enables the medical officer of health to enter any public elementary school within the borough at all reasonable times and to examine the scholars attending such school. It also insures that the occupier of any inhabited building wherein there is, or has been recently, any person suffering from a dangerous infectious disease shall, upon the request of the medical officer of health, furnish to him such information as he may reasonably require. Dr. Richards is clearly somewhat anxious as regards a large portion of the water-supply of Croydon, the whole of which is derived, save for a certain part furnished by the London Water Board, from wells in the chalk. Some of this chalk is hereabouts covered with tertiary formations, while other parts of it are uncovered, and it would seem from Dr. Richards's observations that the chalk in the vicinity of Croydon is known to be fissured in places. As he observes, the question resolves itself into this: Can unpurified sewage gain access to the wells? There have been two epidemics of enteric fever in Croydon, one in 1853 and another in 1875, and in neither of these cases could the influence of the water be altogether put aside. In consequence of the last outbreak the wells were lined for a greater depth than was the case formerly but Dr. Richards fears that it is doubtful whether the record of the last 30 years can long be maintained. One of the wells has actually been abandoned in consequence of the contamination of its water and "the connexion between all four wells is so intimate that there is no guarantee that the remaining wells may not suffer a similar misfortune, especially as the area from which the wells derive their supply is becoming more and more thickly populated. The reality of this risk is emphasised by the fact that bacteriological examination already indicates occasional departures from the high standard of purity which should be maintained by wells in the chalk. A fissure is known to exist from Surrey-street (where there are several wells) to the Addington Hills and there must

1·4 in Edinburgh. The six fatal cases of whooping-cough exceeded the number recorded in any previous week of the year, the deaths from this cause in the three preceding weeks being two, one, and four. The 136 deaths from all causes in Dublin last week included 25 of infants under one year of age and 32 of persons aged upwards of 60 years. Four inquest cases and two deaths from violence were registered. The deaths occurring in public institutions numbered 61, or nearly 45 per cent., of the total deaths; in London the proportion was 42 per cent. The causes of two, or nearly 1·5 per cent., of the deaths registered in Dublin last week were not certified either by a registered medical practitioner or by a coroner; in London only one of the 1072 deaths was uncertified, while in Edinburgh the proportion was 11·6 per cent.

VITAL STATISTICS OF LONDON DURING JUNE, 1906.

IN the accompanying table will be found summarised complete statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases it appears that the number of persons reported to be suffering from one or other of the nine diseases specified in the table was equal to an annual rate of 7·6 per 1000 of the population, estimated at 4,721,217 persons in the middle of the year. In the three preceding months the rates had been 5·7, 5·9, and 6·4 per 1000 respectively. The lowest rates last month were recorded in Kensington, Hampstead, Stoke Newington, Holborn, Poplar, and Lewisham; and the highest rates in Finsbury, the City of London, Shoreditch, Stepney, Bermondsey, and Greenwich. Ten cases of small-pox were notified last month, against seven, one, and six in the three preceding months; of these ten cases, six belonged to Camberwell, two to Hackney, and one each to Paddington and Bethnal Green. The Metropolitan Asylums hospitals contained 11 small-pox patients at the end of last month, against ten, six, and five at the end of the three preceding months. The prevalence of scarlet fever showed a slight excess in June as compared with the previous months of this year; this disease was proportionally most prevalent in the City of London and in the boroughs of Hammersmith, Shoreditch, Stepney, Bermondsey, Battersea, and Greenwich. The Metropolitan Asylums hospitals contained 2705 scarlet fever patients at the end of last month, against 2353, 2192, and 2462 at the end of the three preceding months; the weekly admissions averaged 354, against 238, 282, and 321 in the three preceding months. Diphtheria was considerably more prevalent than in the preceding month; the greatest proportional prevalence of this disease was recorded in Fulham, Finsbury, Stepney, Bermondsey, and Greenwich. The number of diphtheria patients in the Metropolitan Asylums hospitals, which had been 924, 860, and 760 at the end of the three preceding months, had risen again to 782 at the end of last month; the weekly admissions averaged 114, against 111, 103, and 98 in the three preceding months. The prevalence of enteric fever was greater last month than in any other recent month; amongst the various metropolitan boroughs this disease was proportionally most prevalent in Chelsea, Islington, Finsbury, Bethnal Green, Southwark, and Lambeth. There were 93 enteric fever patients under treatment in the Metropolitan Asylums hospitals at the end of last month, against 65, 56, and 41 at the end of the three preceding months; the weekly admissions averaged 20, against 11, 11, and 12 in the three preceding months. Erysipelas was proportionally most prevalent in Hammersmith, Chelsea, St. Pancras, Stepney, Bermondsey, and Wandsworth. The 17 cases of puerperal fever included five belonging to Islington and three each to Finsbury and Lambeth.

The mortality statistics in the table relate to the deaths of persons actually belonging to the various boroughs, the deaths occurring in public institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ending June 30th 4305 deaths of persons belonging to London were registered, equal to an annual rate of 11·9 per 1000 of the population; in the three preceding months the rates had been 16·2, 17·0, and 13·8 per 1000. The death-rates last month ranged from 8·0 in Hampstead, 8·2 in Woolwich, 8·4 in Lewisham, 9·1 in Stoke Newington, and 9·4 in Hackney and Battersea, to 14·7 in Shoreditch and in Bethnal Green, 15·5 in Bermondsey, 15·9 in Holborn and in the City of London, 16·4 in Chelsea, and 17·4 in Finsbury. The 4305 deaths from all causes in London last month included 436 which were referred to the principal infectious diseases; of these, 198 resulted from measles, 39 from scarlet fever, 34 from diphtheria, 77 from whooping-cough, 20 from enteric fever, and 68 from diarrhœa. No death from any of these diseases was recorded in the City of London; among the metropolitan boroughs they caused the lowest rates in the City of Westminster, Hampstead, Stoke Newington, Lewisham, and Woolwich; and the highest rates in St. Pancras, Holborn, Finsbury, Shoreditch, Bethnal Green, Poplar, and Bermondsey. The 198 deaths from measles were slightly above the corrected average number in the corresponding periods of the four preceding years; this disease was proportionally most fatal in St. Pancras, Holborn, Finsbury, Shoreditch, Poplar, and Bermondsey. The 39 fatal cases of scarlet fever were seven in excess of the corrected average number; the greatest proportional mortality from this disease occurred in Paddington, Hammersmith, Chelsea, St. Pancras, Bethnal Green, Stepney, Bermondsey, and Lambeth. The 34 deaths from diphtheria were 11 fewer than the average for the corresponding periods of the four preceding years; among the various metropolitan boroughs diphtheria was proportionally most fatal in the City of Westminster, St. Marylebone, Finsbury, Stepney, and Lambeth. The 77 fatal cases of whooping-cough showed a decline of 44 from the corrected average number; the highest death-rates from this disease were recorded in Holborn, Finsbury, Shoreditch, Bethnal Green, Bermondsey, Battersea, and Wandsworth. The 20 deaths from "fever" were slightly in excess of the average for the corresponding periods of the four preceding years; of these 20 deaths three belonged to Islington, two each to St. Pancras and Southwark, and one each to 13 other boroughs. The 68 fatal cases of diarrhœa were considerably below the corrected average number; among the various metropolitan boroughs this disease was proportionally most fatal in Paddington, Fulham, Shoreditch, Southwark, Bermondsey, Camberwell, and Deptford. In conclusion, it may be stated that the aggregate mortality in London last month from the principal infectious diseases was nearly 16 per cent. below the average.

Infant mortality, measured by the proportion of deaths among children under one year of age to registered births, was equal to 85 per 1000. The lowest rates of infant mortality were recorded in Paddington, St. Marylebone, the City of London, Wandsworth, Lewisham, and Woolwich; and the highest rates in Kensington, Chelsea, the City of Westminster, St. Pancras, Holborn, and Shoreditch.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet Surgeons: J. Ll. Thomas to the *Pembroke*; W. Hackett to the *President*, for three months' course at West London Hospital. Staff Surgeons: E. G. E. O'Leary to the *Thetis*, on recommissioning; M. J. Smith and H. W. B. Shewell to the *President*, for three months' course at West London Hospital. Surgeons: A. I. Sheldon to the *Astræa*, and on recommissioning; P. G. Williams to the *Alacrity*, and on recommissioning; W. G. M. Anderson to the *Impregnable*, for the *Inconstant*; T. B. Shaw to the Royal Naval Rendezvous, lent; R. R. Horley to the *President*, for three months' course at West London Hospital; B. Pick, lent to Portland Hospital; J. J. H. Rooney to the *Blake*; W. Bastian to the *President*, for three months' course at West London Hospital; J. G. Watt to the *Sirius*; and P. L. Crosbie and J. H. le B. Page to the *Vivid*.

In accordance with the provisions of Her late Majesty's Order in Council of April 1st, 1881, Surgeon George Edward Glynn has been placed on the Retired List (dated July 5th, 1906); Surgeon Frederick Francis Mahon has been promoted to the rank of Staff Surgeon in His Majesty's Fleet (dated July 11th, 1906).

ROYAL ARMY MEDICAL CORPS.

Lieutenant-Colonel John M. Nicolls retires on retired pay (dated July 14th, 1906). Captain Arthur E. Milner to be Major (dated April 28th, 1906).

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING JUNE, 1906.

(Specially compiled for THE LANCET.*)*

CITIES AND BOROUGHS.	Estimated population in the middle of 1906.	NOTIFIED CASES OF INFECTIOUS DISEASE.											DEATHS FROM PRINCIPAL INFECTIOUS DISEASES.											Deaths from all causes.	Death-rate per 1000 living.	Deaths of infants under one year to 1000 births.

* Including membranous croup.

4. A piece of tissue removed from the uterus was handed to me recently wrapped in lint for examination. On unfolding it the well-known and peculiar smell of the placenta at childbirth—as far as my experience, a somewhat limited one, goes pathognomonic of pregnancy and not present in ordinary endometritic scrapings—was very noticeable. Would one be justified on this sign alone, unaccompanied by a microscopical examination, in swearing in a court of law that such tissue was placental in origin? If, as I believe, the smell *is* distinctive, it is perhaps a more reliable test even than the examination of a section, the only fault being that a "smell" cannot be "registered," so that other opinions may confirm that of the first observer.

These examples may, perhaps, show that too little use is often made of this much-despised sense of ours and that it may not only aid us materially in coming to a right conclusion but may also sometimes be our only guide.

I am, Sirs, yours faithfully,
J. BURTON CLELAND, M.D., Ch.M. Sydney,
Late Cancer Research Scholar, London Hospital;
Government Bacteriologist and Pathologist,
Perth, Western Australia.

Perth, Western Australia, June 15th, 1906.

THE PUBLIC HEALTH AND THE IMPORTATION OF FOREIGN CARCASSES.

To the Editors of THE LANCET.

SIRS,—The revelations concerning Chicago packing-house methods seem to have awakened amongst the majority of the general public a feeling of uneasiness as regards canned meats only. They look upon the chilled and frozen carcasses which we receive from America as a little inferior to English meat, but any suspicions as to its wholesomeness rarely enter their minds. Whilst I believe that it is the intention of our Government to take steps to safeguard the wholesomeness of the former class of goods, something should also be done to deal with the importation of the carcasses of foreign meat, especially as it forms such a very large proportion of our meat-supply. At the present time our inspection of such carcasses is always rendered very uncertain and must be so until we make more stringent laws. We might with advantage to ourselves frame regulations similar to those of Germany which govern the introduction of foreign meat into that country. There, as you know, such meat, whether fresh, chilled, or frozen, can only be imported in the entire carcasses, with the pleura, peritoneum, heart, lungs, kidneys, as well as the udder in cows, attached in "natural connexion." Even with these organs it is not possible always to be correct in one's judgment; yet how much more difficult must it be to give a satisfactory one from the examination our inspectors are able to make.

During the late meat famine in Germany our meat salesmen sent over there the carcasses of American cattle which had been slaughtered on their arrival at Deptford or Birkenhead. Our butchers complied with the German law as to the attachment of the internal organs, &c., and sent only the carcasses of those beasts whose internal organs were perfectly healthy, as the slightest trace of disease would preclude the passing of the carcasses as fit for food in Germany. At the same time numbers of carcasses whose internal organs presented lesions which here in England were sufficient to condemn the organs affected but not the whole carcass were not sent to Germany but dressed for sale in the English markets.

Surely if we in England will go to this trouble for our foreign customers it is not too much to ask that foreigners be made to do the same for us. As it is, if they choose, no matter what the condition of the internal organs might be if the rest of the carcass was apparently healthy, it would be good enough for England though not good enough for Germany.

I am, Sirs, yours faithfully,
J. F. HODGSON,
Deputy Medical Officer of Health.

Halifax, July 16th, 1906.

THE CAUSES OF LEPROSY.

To the Editors of THE LANCET.

SIRS,—Turkey in general, and Constantinople in particular, afford a very favourable field for the study of leprosy. The Ottoman capital possesses a large hospital for patients suffering from that terrible disease. It is, besides, not an uncommon sight here to meet lepers in all stages of disfigurement moving about quite freely in the streets. I have at present under my treatment two cases of leprosy and the following facts concerning them might not be without interest. The first case is that of a man about 30 years of age. He is a Jew and a member of a numerous family. They all live in one house. With the exception, however, of my patient, who is very badly disfigured, and his mother, whose symptoms of leprosy are manifested in the leonine appearance of her face, all the rest of the family—grandparents, father, two brothers, and five sisters—are perfectly healthy. As all these people lived for many years in one house, aggregating for the most part of the day in one room; as they frequently partake of their meals with one and the same spoon or fork and from one and the same dish, sometimes helping themselves quite in the oriental fashion by dipping into it their fingers (the use of forks and knives is not yet quite universal here); and as one towel, one napkin, and one sheet (I have very carefully ascertained the fact) are continually employed by all the members of the family, my patient included, who has a number of ulcerating sores on the whole of his body as well as on his face,—is it not striking that only two people are affected by the loathsome disease and that the rest enjoy what appears to be a perfect immunity? My other case is even more striking. A man, also a Jew, about 40 years of age, whose face, nose, ears, lips, eyelids and hands are literally eaten away by leprosy, affording an awful sight of mutilation, shared one small room and one bed with his old father for over 20 years. Yet the old man is perfectly free from every symptom, in spite of the fact that here, too, the same conditions and circumstances of closest intercourse, as enumerated in my first case, prevailed. The question of contagiousness or infectiousness of leprosy appears to me, therefore, in view of the above facts, to point to a negative answer.

As to the fish causation theory, so sedulously propounded by Mr. Jonathan Hutchinson, I would like to submit the following consideration. If there are places in the world where bad fish of every possible form and description, cured and uncured, are consumed in astonishingly large quantities, these places are to be found in the districts and suburbs on the banks of the Bosphorus and of the Golden Horn. Yet leprosy is there exceedingly rare and in many parts has never been known to exist. As emigration among the indigenous poor classes of the Jewish, Greek, and Armenian population (and it is these classes that enjoy so much the consuming of bad fish, especially of the so-called improperly cured *haringha*) very seldom, or almost never, takes place, the argument cannot be put forward that the infected elements might show the manifestations of the disease of leprosy after quitting the country. Then, again, in my two leprotic cases the *haringha*, very often stinking and only half cured, has been for many years a favourite dish, frequently eaten with salads, and yet the greater majority of members remained quite unaffected. I venture to think that as long as the real nature and the biological conditions of the bacillus lepræ are not exactly known the question of causation of leprosy, as well as of its contagiousness or infectiousness, will remain a debatable one.

I am, Sirs, yours faithfully,
DAVID SANDLER.

British Post Office, Constantinople, July 12th, 1906.

DENDRITES AND DISEASE.

To the Editors of THE LANCET.

SIRS,—May I be permitted to draw attention to certain remarks made by Sir William Gowers in his lecture on Dendrites and Disease, published in THE LANCET of July 14th, p. 67. In the first place, he states without any qualifying remarks that the terminal branchings of the nerve cell processes do not unite, "they end in contiguity to others, not in continuity with them." This is a view by no means universally held at the present time by neuro-histologists; and, moreover, it is one which year by year as new appearances are brought to light in nervous tissue by more delicate technique is becoming more widely doubted. Sir William Gowers confines his remarks on what he terms "facts of structure" in nervous tissue to appearances presented by this tissue after treatment with silver, according to one or another modification of Golgi's method. On the vexed question of thorns or gemmules he says: "By silver staining they [the dendrites] are revealed and seen to end in

INDIAN MEDICAL SERVICE.

The King has approved of the retirement from the Service of the undermentioned officer:—Lieutenant-Colonel Joseph William Townsend Anderson (dated April 15th, 1906).

ARMY MEDICAL RESERVE OF OFFICERS.

Surgeon-Major David Lennox to be Surgeon-Lieutenant-Colonel (dated June 15th, 1906).

VOLUNTEER CORPS.

Royal Garrison Artillery (Volunteers): 1st Gloucestershire: Surgeon-Lieutenant A. Ogilvy to be Surgeon-Captain (dated July 18th, 1906).

Royal Engineers (Volunteers): 1st Devonshire and Somersetshire: Surgeon-Lieutenant-Colonel G. B. Fraser is granted the honorary rank of Surgeon-Colonel (dated July 17th, 1906); Surgeon-Lieutenant-Colonel and Honorary Surgeon-Colonel G. B Fraser resigns his commission, with permission to retain his rank and to wear the prescribed uniform (dated July 18th, 1906).

Rifle: The Queen's Rifle Volunteer Brigade the Royal Scots (Lothian Regiment): Surgeon-Major A. D. Webster is borne as Supernumerary whilst holding the appointment of Brigade-Surgeon-Lieutenant-Colonel, Senior Medical Officer, 1st Lothian Volunteer Infantry Brigade (dated July 18th, 1906). 1st Volunteer Battalion the Lincolnshire Regiment: Surgeon-Lieutenant A. S. Green to be Surgeon-Captain (dated July 18th, 1906). 4th Volunteer Battalion the Cheshire Regiment: Second Lieutenant R. Ollerenshaw resigns his commission (dated July 18th, 1906); Robert Ollerenshaw (late Second Lieutenant) to be Surgeon-Lieutenant (dated July 18th, 1906). 1st (Brecknockshire) Volunteer Battalion the South Wales Borderers: William Lewis Pritchard to be Surgeon-Lieutenant (dated July 18th, 1906). 2nd Volunteer Battalion the Sherwood Foresters (Nottinghamshire and Derby shire Regiment): Surgeon-Lieutenant J. Buckley resigns his commission (dated July 18th, 1906). 1st Nottinghamshire (Robin Hood) Volunteer Rifle Corps: Surgeon-Lieutenant R. P. Shearer is removed from the Volunteer Force for failing to fulfil the prescribed conditions for efficiency (dated June 20th, 1906).

A FIELD HOSPITAL BURNT.

A telegram in the *Morning Leader* of July 16th, dated Durban, Sunday, states that the field hospital at Thring's Post has been destroyed by sparks from a rubbish fire. All the patients were saved but the kit was lost. The rescue of the patients was of a hazardous nature. Some were removed from the burning tent while cartridges were exploding in every direction.

THE ORGANISATION OF AN AUXILIARY MEDICAL SERVICE FOR WAR.

Captain W. Salisbury Sharpe, Royal Army Medical Corps (Volunteers), contributes to the *Journal of Preventive Medicine* for July an interesting article on the above subject in which he says: "Let us, as medical men, record the fact that we appreciate the necessity of universal service, and in the meantime try to maintain and improve the auxiliary services as a stem on which the larger service may be grafted, for we must recognise as a grave error the present tendency to break down the existing service by imposing impossibly onerous conditions, and, having done so, to cast it aside as a failure, and start anew to draw out a wider plan." He discusses his subject under the following heads: (1) Royal Army Medical Corps conditions necessitating auxiliary aid in war; (2) the existing auxiliary medical services, their adaptation for peace conditions and their want of adaptation for war conditions; (3) the kind of auxiliary aid required in war—viz., officers, men, transport, and material; and (4) means of meeting these needs.

THE ADMIRALTY AND PHYSICAL TRAINING.

In a circular letter issued on July 9th to the commander-in-chief of fleets and stations the Admiralty directs that in future the whole staff of the engine-room department of ships are to undergo physical training as far as circumstances permit in connexion with their duties. The instruction will be given by the executive officer who is responsible for physical training, subject, however, to the supervision of the engineer officer, who is also to be consulted as to when the services of the engine-room ratings and stokers can best be spared for physical drill.

DISTRIBUTION OF PRIZES AT HASLAR.

The course of instruction for surgeons of the Royal Navy at Haslar was brought to a close on July 2nd when the prizes were distributed by the Director-General of the Medical Service of the Royal Navy. The gold medal was awarded to Surgeon L. L. Greig of the University of Glasgow, the microscope to Surgeon L. Warren of the London Hospital, and the silver medal and books to Surgeon R. C. P. McDonagh of St. Bartholomew's Hospital. The names of the candidates with the marks gained are as follows:—

Leonard Warren	4610	Percy P. Minett	[illegible]
Louis L. Greig	4447	Frederick G. Goble	[illegible]
Reginald C. P. McDonagh	4168	John Bourdas	[illegible]
Ewen Cameron	4128	*Herbert A. Browning ...	–

* This officer could not attend the second part of the examination owing to illness.

"Audi alteram partem."

THE SENSE OF SMELL AS AN AID IN DIAGNOSIS.

To the Editors of THE LANCET.

SIRS,—The importance of the sense of smell in clinical diagnosis has sunk almost into insignificance before that of sight or even that of hearing. This is in part due to its poor development in many persons but also to neglect of its use. Bacteriology has adopted it to some extent in noticing the characteristic odours of certain cultures, but it seems to me that in some cases it is of material aid at the bedside and may with reason be admitted to medico-legal importance. One or two instances of its services in these respects may suggest others and will suffice in calling attention to its numerous applications.

1. The smell of acetone in the breath of patients with diabetic coma is well known. An instance in which this sign preceded by some hours the onset of untoward symptoms made a great impression upon me as a student. On entering a long ward containing 32 beds I approached the house physician who was examining a patient new to me. As I came near a strong ethereal smell was very noticeable and I asked the physician at once why an anæsthetic had been given, the ward being a medical one. None had, and on second thoughts—or rather a second smell—the odour was not that of ether but of acetone. Within a few hours, though at the time no suspicious symptoms were present, those of diabetic coma supervened with a fatal result.

2. Nurses in frequent attendance on typhoid fever patients describe a peculiar "typhoid" smell which, from a reliable observer, may be of great service in doubtful cases. The nurses in charge of the plague hospital at Perth, Western Australia, assure me that the patients there have a special and distinctive "sour" smell which, since my attention was called to it, I have noticed myself; still, I cannot place sufficient reliance on it as yet in my own case to consider it a certain diagnostic sign. They inform me that on entering a room where a supposed plague patient is lying they can tell at once by this means whether it is a genuine case or not. Other infectious diseases have well-known and oft-described pathognomonic smells.

3. Rheumatic fever has a characteristic sour smell associated with its acid perspiration. Some years ago I was giving an anæsthetic for a supposed case of appendicitis in a girl in whom the usual symptoms and signs of that affection were present. During the administration the patient's perspiration attracted my attention from its peculiar rheumatic-like smell. To our astonishment the appendix was found to be perfectly normal. Now the evening before I had been reading Treves's "System of Surgery" and had come upon a reference to a rheumatic affection which simulated appendicitis. Bearing in mind the peculiar odour I had noticed and mentioning it, I hazarded the suggestion that this might be a case in point. The patient was removed from the operating table, but though the wound itself showed no sign of suppuration endocarditis and pericarditis developed and death followed. Was this a mere coincidence and not a manifestation of acute rheumatism or was the hypothetical diagnosis, based on the sense of smell, in reality the correct one?

dead and the hair began to grow again before the month was over. The cases of tinea circinata under this treatment disappear like *magic under one application.* Of course, in many cases of tinea tonsurans more than one application may be found necessary but never more than three. The efficacy of formic aldehyde in the treatment of ringworm is, no doubt, in great part due to the pungency of the vapour which penetrates down into the hair follicles and destroys the cocci. I am, Sirs, yours faithfully,

Tetbury, Glos., July 14th, 1906. DESBOROUGH BRODIE.

A FAMILY TENDENCY TOWARDS FRACTURE OF THE PATELLA.

To the Editors of THE LANCET.

SIRS,—The following series of facts is, I think, of some general interest and therefore worth recording.

In the Westminster Hospital, under Mr. C. Stonham, senior surgeon, there is at the present time a patient, aged 38 years, with a transverse fracture of his right patella. Nine years ago the same man fractured the left patella. His father when 20 years of age fractured his left patella; one brother when 32 years old fractured his right patella; and another brother at the age of 35 years also broke his right patella. All accidents were the result of indirect violence, and all are healthy men and carry on different trades. I am, Sirs, yours faithfully,

J. H. HEBB,
House Surgeon.

July 14th, 1906.

MUMPS AS AN AILMENT OF ADULTS IN THE ARMY.

To the Editors of THE LANCET.

SIRS,—I should like to add a word or two in support of the efforts made by recent writers to secure more serious consideration for the disease known as *mumps*, for the malady is still regarded by the majority of people as of a trivial character.

A small outbreak occurred among some troops under my medical care. There were only 11 cases but no less than five of these had complications of a severe nature. Four men had orchitis which, in at least one case, will probably lead to atrophy of the testicle or testicles (one man having had double orchitis). In three instances it was orchitis which led to the diagnosis. One man had double iritis on the twelfth day after onset of the disease. In three cases the temperature was 104° F. for more than one day—one of these men had intense headache and delirium, indicating cerebral disorder. The remaining complication or rather sequel took the form of great weakness of the lower limbs, which symptom became marked in one man after he had returned to duty. The patients were all isolated—the total loss of working days was therefore considerable. The cases are of recent date and may yet be followed by serious after-effects, such as, for instance, deafness.

I am, Sirs, yours faithfully,
F. SMITH,
Major, Royal Army Medical Corps.

NOTES OF TWO OUTBREAKS OF DIPHTHERIA SUCCESSFULLY STAMPED OUT BY THE FREE USE OF PROPHYLACTIC INJECTIONS OF DIPHTHERIA ANTITOXIN.

To the Editors of THE LANCET.

SIRS,—The free use of prophylactic injections of diphtheria antitoxin has proved so successful in *stamping out* outbreaks of diphtheria in two very susceptible communities under my care that the instances seem worthy of record.

1. In a girls' school containing 16 boarders and six day scholars a boarder fell ill on March 13th, 1906, with diphtheria. The following measures were at once taken: (1) the school was broken up; (2) all the day scholars received a prophylactic injection; (3) all the boarders were sent to their homes with a strongly worded appeal that they should receive an injection (in 13 instances this advice was taken; in two cases isolation and medical supervision were substituted); and (4) the mistresses and inmates of the school-house were injected. These measures were completely successful and no second case occurred.

2. In a second and contiguous girls' school containing 60 to 70 day scholars and six boarders, a day scholar fell ill with diphtheria on March 23rd, 1906 As this scholar had attended school for some days no further steps were taken than the injecting of the child's household and a notification to the head mistress to at once report any case of illness. On March 29th, however, a second day scholar fell ill with the disease The school being too numerous to inject in every case I judged it sufficient (1) to inject all the classmates of the two cases; (2) all the boarders; (3) a few other scholars who, being friendly with one or other of the two cases, were known to be contacts; (4) the school was broken up; and (5) all parents were requested to notify at once any case of illness. No further case occurred.

The following general remarks suggest themselves to me. The prophylactic injection used in each case was 1000 units. Each of the three cases was of a severe type and in each case Klebs-Löffler bacilli were proved to be present. None of the children developed any serum disease. Two of the adults developed transient urticaria and one muscular pains in addition lasting a few days. No connexion could be traced between the outbreaks in the two schools; this connexion, however, must have occurred, as there have been no other cases of this disease in the neighbourhood for a considerable time and the interval of ten days between the cases is about the time which experience has taught me a contact is usually found to be suffering from the disease. When one thinks of the ease with which these two outbreaks were stamped out without loss of life and without any serious trouble or risk one cannot be too thankful that we have at our command so potent a preventive as the serum. Without serum the outbreaks would probably have spread widely, as the two schools are attended by children of all ages from five to 16 in constant association with each other, both in and out of school.

I am, Sirs, yours faithfully,
WILLIAM BLIGH, M.D., B.S. Lond.

Caterham Valley, July 14th, 1906.

INACCURATE TEXT-BOOKS.

To the Editors of THE LANCET.

SIRS,—The position of a medical man working a general practice single-handed and at the same time attempting to read for the D.P.H is not an enviable one, for he is absolutely dependent for his knowledge upon his reading altogether unaided by the systematic teaching of his hospital days. How important then is it to be able to rely upon a good, sound, up-to-date text-book as a foundation for one's reading. With this object I obtained a certain well-known text-book, which has been before the public 16 years, and of which a revised edition appeared less than a year ago. From this I have already learnt the following astonishing facts. That air contains 5 per cent of argon; that proof spirit contains only 42 7 per cent. absolute alcohol by volume; that rectified spirit contains 16 per cent. of water; that the formula for milk-sugar or lactose is $C_{12}H_{24}O_{12}$, and that of stearin $C_{21}H_{40}O_6$; that the proper way to join a drain to a sewer is to connect the drain with the *lower* half diameter of the sewer; that potassium *bi*chromate—i.e., the red chromate—is the usual test for lead; that in making a quantitative examination for calcium in water the amount should be calculated from the weight of the calcium oxide formed by ignition; that Gaertner's bacillus ferments lactose and sometimes dextrose (in this statement I think the authors have Muir and Ritchie on their side but no one else); that—but what need to continue? Surely, Sirs, it would go hard with one if he made such statements before the examiners.

I am, Sirs, yours faithfully,
BETA.

July 14th, 1906.

⁂ Two examples which "Beta" gives are surely not inaccuracies. It is the fact, for instance, that rectified spirit contains 16 per cent. of water and, again, $C_{12}H_{24}O_{12}$ is the correct though empirical formula for milk-sugar. It is, of course, better represented as $C_{12}H_{22}O_{11},H_2O$.—ED.L.

a small knob or in a point, and their terminal portion bears small bud-like projections on the surface. It is this fact of their termination (discovered by Ramon y Cajal) which is relied on as evidence of the discontinuity of the neurons."

Now, whilst it is perfectly true that in silver impregnated tissue the appearance is such as he describes, surely this is no warrant for definitely concluding that because this particular method fails to show anything in structural relationship to the apparently terminal knobs therefore nothing exists. The neuron doctrine must be in a parlous state if it has to rely upon appearances revealed by one method which are refuted by other and more delicate methods.

Methylene blue when appropriately applied forms the basis of one of these newer methods which reveals structures infinitely more delicate than those shown by the silver impregnation used by Ramon y Cajal. It gives a picture which throws grave doubts on the accuracy of much that is shown by silver. Amongst other new details which it reveals it clearly shows that the little lateral projections appearing as terminal by the silver impregnation method are in reality long beaded fibrils, the course of which can often be traced in the matrix for very considerable distances. Dr. Alexander Hill long ago pointed this out even in silver preparations which do occasionally show it.

Finally, Sir William Gowers is not quite accurate when he states that "before staining agents can reveal structure hardening agents have to increase the consistence of the substance and multiply many times any original difference that exists." This does not quite apply either to Ehrlich's "vital" method or that which I have described as the "pseudo-vital" method. In both of these the stain is applied to the tissue prior to any hardening agent and in both cases with very little question success depends upon chemical interchanges between the tissue and the stain, which the addition of a hardening agent would render impossible. I am, Sirs, yours faithfully,

JOHN TURNER.

Essex County Asylum, Brentwood, July 14th, 1906.

THE WORKMEN'S COMPENSATION BILL.

To the Editors of THE LANCET.

SIRS,—On comparing the above Bill as recently amended in Committee with the extracts from the printed Bill of paragraphs affecting the medical profession which appeared in THE LANCET of April 21st last I find that the only alteration made is in Paragraph 15 of the first schedule. By the first alteration the workman is placed on an equality with the employer as to being able to obtain the certificate of his own medical attendant and use it, and I believe this will be considered as only just. In the second alteration the medical referee may in his discretion, in certain circumstances, decline to give a certificate. I think in this case he should be required shortly to state the grounds for his refusal for the information of all parties interested. I have put the additions to the clause in italics.

First Schedule (15).—A workman shall not be required to submit himself for examination by a medical practitioner under paragraph (4) or paragraph (14) of this schedule otherwise than in accordance with regulations made by the Secretary of State, or at more frequent intervals than may be prescribed by these regulations. Where a workman has so submitted himself for examination by a medical practitioner, *or has been examined by a medical practitioner selected by himself, and the employer or the workman, as the case may be*, has within six days after such examination furnished *the other* with a copy of the report of that practitioner as to the workman's condition, then in the event of no agreement being come to between the employer and the workman as to the workman's condition or fitness for employment, the registrar of a county court on application being made by *either party*—(a) may, on payment by the applicant of such fee not exceeding £2 as may be prescribed if the application is made before the amount of the weekly payment is settled; and (b) shall without any fee if the application is made for the purposes of review after the weekly payment is settled, refer the matter to a medical referee. The medical referee to whom the matter is so referred shall, in accordance with regulations made by the Secretary of State, give a certificate as to the condition of the workman and his fitness for employment, specifying, where necessary, the kind of employment for which he is fit, and that certificate shall be conclusive evidence as to the matters so certified. Where no agreement can be come to between the employer and the workman as to whether or to what extent the incapacity of the workman is due to the accident, the provisions of this paragraph shall apply, if both parties so agree in writing, as if the question were a question as to the condition of the workman, *provided that the medical referee, if he considers that the evidence before him is not sufficient to enable him to give a conclusive decision, may decline to give a certificate.*

I am, Sirs, yours faithfully,
ALBERT BENTHALL, F.R.C.P. Edin., &c.

Fellows-road, N.W., July 10th, 1906.

A NEW METHOD OF STAINING ENCAPSULATED MICRO-ORGANISMS.

To the Editors of THE LANCET.

SIRS,—Many methods of staining to show simultaneously the organism and its capsule have been recommended from time to time but none of them have been at all certain in their results. In these circumstances it might be worth while to record that with the following method we have been able to get satisfactory and certain results here. The specimen is first stained from three-quarters of a minute to one minute in the ordinary carbol-fuchsin solution and then afterwards for one minute in the following solution as a differential stain: mercuric chloride, 0 1 gramme; and water and alcohol, of each 25 cubic centimetres. The micro-organisms are stained bright red and are clearly seen; the capsule remains colourless against the general pink ground. This stain is permanent and I think can safely be recommended for demonstrating encapsulated organisms. In staining sputa the specimen should be kept for one and a half minutes in the carbol-fuchsin and for two minutes in the special solution.—I am, Sirs, yours faithfully,

DR. HANS SCHÄDEL.

Pathological Laboratory, "Dreadnought" Hospital,
Greenwich, S.E., July 14th, 1906.

HYGIENIC MEASURES AGAINST SYPHILIS.

To the Editors of THE LANCET.

SIRS,—Dr. C. R. Niven asks "What is morality?" He may remember a definition in Professor T. Clifford Allbutt's "System of Medicine" that "The essential of vice is the instant indulgence of desire at the cost of future disadvantage." I know no clearer statement than this of the real meaning of immorality which can thus hardly be said to be "a matter of instinct rather than of ratiocination." And certainly it is by no means rare to find in England that vice is avoided simply because it is not worth the risk of venereal disease. Not a high motive truly, but sufficient to prove that desire is not so ungovernable as Dr. Niven would seem to believe. By removing the hedge of the risk of syphilis from the margins of "the narrow way" we simply should eliminate an important restraint, especially for that increasing class whose actions are becoming more and more influenced by reason than by instinct. But has Dr. Niven any figures to bring forward to prove that "regulation of vice" *does* limit the ravages of venereal disease? No. The real fight against syphilis should be part of the campaign against luxury, which, for example, prevents the well-educated, decently born, industrious, and temperate medical man from marrying and having a family till he is 30–35 years of age.—I am, Sirs, yours faithfully,

Manchester Fever Hospital, July 7th, 1906. ERIC M. WILKINS.

THE TREATMENT OF RINGWORM.

To the Editors of THE LANCET.

SIRS,—I was very much interested in Mr. T. Jackson's letter on the treatment of ringworm in THE LANCET of June 30th and I am glad to see that there are still some who appreciate the value of less expensive treatment than that of manifold exposures to the x rays for that troublesome disease. For a short time I used liquor epispasticus in much the same way as Mr. Jackson suggests, but instead of diluting it with glycerine I used the full strength. On the whole the results were satisfactory and I was pleased with my success, until I was called in to see a man whom I had treated in this way. He was suffering from acute headache and sickness, his face was puffy, and his urine was thick with albumin. Luckily the nephritis was transient and disappeared after hot packs and purgatives had been exhibited. Since that time I have had many opportunities of carrying out the line of treatment as suggested by Mr. J. Stafford Mellish in the *Hospital* of June 30th—namely, the rubbing in of formic aldehyde (40 per cent.). The cures are quicker and more certain than with liquor epispasticus and there is no danger of setting up acute nephritis. The worst case of ringworm which I have ever seen, covering the whole head, was treated by Mr. Mellish a short time back with one rubbing in of formic aldehyde and then the application of ung. hydrarg. oxid. flav. dil. In a fortnight the disease was dead and the hair began to grow again before the month was over. The cases of tinea circinata under this treatment disappear like magic under one application. Of course, in many cases of tinea tonsurans more than one application may be found necessary but never more than three. The efficacy of formic aldehyde in the treatment of ringworm is, no doubt, in great part due to the pungency of the vapour which penetrates down into the hair follicles and destroys the cocci. MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

Salford Workhouse and Infirmary.

AT a recent visit to the Salford workhouse Mr. H. Jenner-Fust, the Local Government Board inspector, gave some criticisms which show that there is still room for improvement in the management. He spoke of the large number of infirm and helpless inmates and suggested that they should be looked after during the night by a paid attendant. He also said that the basement where the old men sat and smoked was a "miserable place," used for peeling potatoes, and he asked that they "should be kept upstairs in the day room. The atmosphere downstairs was not of the best." These improvements may well be carried out without provoking the suspicion that Salford wishes to rival metropolitan Poplar. The establishment of the Culcheth cottage homes has led to the lessening of pressure on the workhouse owing to the removal of many of the children and it was satisfactory to hear of the success of the homes, "the children being extremely healthy and their teeth particularly good." It appears that there are some spare homes at Culcheth which are going to be occupied by children from the Leigh union.

Death of Mr. W. L. Saunder.

The Manchester Royal Infirmary has suffered a severe loss in the death of the general superintendent and secretary, Mr. W. L. Saunder. He died on July 10th, after an illness of several weeks, at the age of 66 years. Appointed secretary in 1878, his service to the infirmary was of 28 years' duration. Sprung from a family of soldiers he passed some of his early years in the Suffolk Regiment and did duty for a time at the Cape of Good Hope. Just before the abolition of purchase he sold out and became secretary to the Royal United Hospital at Bath, which he left for Manchester. He was a disciplinarian but possessed the gift of tact and the power of organisation in a high degree, fostered, no doubt, by his experience of military affairs, and these powers were for the rest of his life devoted freely to the interests of the infirmary, to the great advantage of that institution and the public. He soon gained the confidence of the infirmary authorities and this confidence continued through all the changes that time brought with it among those who year by year sat at the infirmary board.

A Case of Anthrax.

On July 14th the Bradford coroner held an inquest on a wool villeyer, aged 77 years. He had been engaged in manipulating Russian camel-hair. It was stated that he went home from his work about noon on the previous Saturday, complained of pain and felt sick, and had no appetite. The same afternoon he fainted and was unconscious for ten minutes. On the next day he was worse and death took place on Tuesday night. Dr. F. W. Eurich, who made a post-mortem examination, said that the state of the organs and the body generally "was scarcely consistent with deceased having died from anything but anthrax, and as what he did find was consistent with that disease he was of opinion that death was due to anthrax by inhalation." In reply to a question he said that it was rarely possible to find anthrax bacilli 30 hours after death.

Food and the Ship Canal.

The Manchester Ship Canal is in the peculiar position of being righteous against its will. It has been unable to escape from having powers conferred on it to examine, and if need be to condemn, food, while some other ports are in a position of greater freedom and less responsibility. But though the recent decision may for a while, among the unthinking and the manufacturers of inferior foods, tell against its trade, to those who look at the matter from another point of view it will tend to its advantage. The satisfactory passing of severer tests than those applied elsewhere gives a valuable testimonial to the quality of the food-stuffs that come up the canal. Before long surely the tests at all ports of entry will be kept at the same standard but in the meantime the fact that food has come by the Manchester Ship Canal will be a strong point in its favour.

LEEDS.

(FROM OUR OWN CORRESPONDENT.)

The Leeds and West Riding Medico-Chirurgical Society.

THE annual report of this society has just been issued to its members. The session 1905–06 was the thirty-fourth, for the society was founded in the year 1872, meeting for the first time under the presidency of the late Dr. Chadwick, with the late Mr. A. F. McGill and Dr. West Symes as honorary secretaries. The past session has been a remarkably successful one in many respects. Mr. Edward Ward has been an excellent president and his brilliant, amusing, and withal highly instructive introductory address will long be remembered by all who heard it. The society, which draws its members from even a wider area than its name would appear to imply, now includes 333 ordinary members. During the past session 11 meetings have been held—seven ordinary, two pathological, and two clinical. The average attendance of members was 76. At the annual meeting, held on May 4th, Dr. A. H. Bampton of Ilkley was elected president and Mr. Edmund Robinson of Leeds and Dr. W. H. Cheetham of Guiseley were elected vice-presidents. One of the attractions of membership of this society is that its library is amalgamated with that of the medical school of the University, to the use of which and of the reading room members have full access. By this amalgamation the number of books purchased and the number of scientific periodicals taken are much greater than if the two bodies were acting independently.

Post-Graduate Course at the Leeds Public Dispensary.

The first course of post-graduate study at the Leeds Public Dispensary has proved highly successful. That there has been a demand, real though not loudly expressed, for such a course in Leeds has been proved. The honorary staff of the dispensary took up the consideration of instituting such a course some months ago. The success of the inaugural meeting was assured by the presence of Mr. Jonathan Hutchinson who addressed a large meeting of the profession in the new dispensary buildings on April 30th and gave valuable counsel as to how such a course should be conducted. The committee decided that the course should be of an eminently practical character and should consist of demonstrations, clinical and pathological, rather than of lectures, and this policy soon rendered it necessary to limit the class to 25, for a good many more than that number expressed a wish to attend. The course was conducted by six members of the honorary staff, each of whom gave a couple of demonstrations. Mr. H. Littlewood and Mr. B. G. A. Moynihan were invited to deliver a lecture each, the former selecting as his subject "Appendicitis" and the latter "The Treatment of Enlarged Prostate"; Dr. T. Wardrop Griffith gave two demonstrations on pathological specimens and clinical cases of Mitral and Aortic Valvular Disease; Mr. E. F. Trevelyan's afternoons were devoted to selected cases of Infantile Palsy and of Pulmonary Phthisis; Dr. W. H. M. Telling showed cases of Skin Disease and cases of Lung Disease in Childhood; Dr. Douglas Seaton's demonstrations were on cases of general surgical interest; Mr. Michael A. Teale discoursed on the Methodical Examination of the Eye; and Dr. O. O. Gruner gave demonstrations on the Clinical Examination of the Blood. The meetings lasted from one and a half to two hours, were extremely well attended, and were so much appreciated that the secretaries are considering the advisability of arranging for either a repetition of the course or a continuation series of demonstrations to be given.

July 17th.

WALES AND WESTERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENTS.)

The Health of Cornwall in 1905.

THE annual report of vital statistics for the county of Cornwall for 1905 has just been published. This states that during the year 7101 births were registered, corresponding to a rate of 22 per 1000, as compared with 22·31 in 1904. 5133 deaths occurred, giving a rate of 15·90 per 1000, against 14·72 in the previous year. The zymotic death-rate was 0·862 per 1000, compared with 0·573 per 1000 in 1904.

322 cases of infectious diseases were notified, as against 39 in 1904. 15 deaths occurred from typhoid fever.

Rhondda and Pontypridd Water-supply.

About two-thirds of the houses in the Rhondda valleys and most of those in the adjoining town of Pontypridd are supplied with water collected from the high lands and stored in a reservoir of 200,000 gallons capacity situated at the head of the Rhondda Fach or Little Rhondda. From time to time during the past ten years there has been a peaty discolouration of this water and although chemical and bacteriological examination has shown it to be of excellent quality many of the inhabitants, on account of the discolouration, have resorted to questionable supplies from mountain streams and elsewhere, resulting on one occasion in an outbreak of typhoid fever. Although the nature of the gathering ground has from the first suggested the possibility of the water possessing a plumbo-solvent action it is only quite recently that such action has been detected. In one part of the Rhondda urban district there have been definite cases of plumbism and the medical officer of health (Dr. J. D. Jenkins) has deemed it desirable to issue circulars to the inhabitants of the affected area advising them to draw off from the pipes every morning about a gallon of water before using it for drinking purposes. The water supplied to a house in Pontypridd, closely adjoining the Rhondda district, has been examined at the Cardiff and County Laboratory, when 0·31 grain of lead to the gallon was found in one sample and 0·17 grain in another. Both samples were taken on the same day.

Water-supply for Upton Scudamore.

Miss Wheeler of Warminster has given £450 for the purpose of providing a water-supply for the village of Upton Scudamore (Wiltshire).

Provincial Meeting of the Incorporated Society of Medical Officers of Health.

The proceedings connected with the annual provincial meeting of the Incorporated Society of Medical Officers of Health usually occupy only a portion of one day. This year being the jubilee of the society they have been prolonged over two days. On the afternoon of July 14th a meeting, presided over by Sir Shirley F. Murphy, was held in the Guildhall, Bath, when Mr. C. S. Loch, LL D., secretary of the Charity Organisation Society, read a paper upon the Relation of Sanitary Authorities to Charitable Societies, in which he pointed out what these two bodies might do in coöperation both in individual cases and in special areas. He first of all showed that although in recent years there were better health and a lower rate of mortality than formerly, yet there were more dependence on the Poor-law and a larger expenditure of charitable resources. This, he maintained, ought not to be, for increased strength in one quarter should imply additional force in another. Better health should mean greater force of character, more independence, and greater self-support. He insisted that both on the sanitary authorities of the country and on the charities the duty was imposed on behalf of the nation of preventing deterioration and as far as possible the misery that comes with it and of improving the conditions of the poor. He dwelt with emphasis upon the importance of imitation, especially with a low scale of intelligence, as a factor for good or evil. A's clean room makes B's look dirty and one man's open window is discussed by his neighbour who fastens his own down. He advocated the appointment of health visitors who should act in close coöperation with the medical officer of health but who should take no active part in the administration of relief, although they should be in constant touch with the officers of the Poor-law and with charitable societies. In the discussion which followed there was a general agreement with the views of the reader of the paper, although Dr. J. B. Kaye expressed a doubt as to the willingness of the ratepayer to set up a separate centre for health visiting and cognate work.—Dr. D. S. Davies considered that charitable societies might very well come closer together and work in greater unity with sanitary authorities.—Sir Charles A. Cameron said that already in Dublin there was much useful work done in the direction desired by Mr. Loch, and Dr. Lionel A. Weatherly considered that the coöperation indicated would be of inestimable value in preventing the spread of consumption. He described as a crying scandal the fact that only 23 of the 679 boards of guardians in this country were doing anything to treat people who were suffering from the disease.—In the evening the members of the society and others dined together at the Empire Hotel. Mr. D. Maclean, M.P., gave the members a message from the President of the Local Government Board, in which he attributed the improvement of the condition of the people to the efforts of medical officers of health. In proposing the toast of the society, Mr. Maclean said that he hoped that the Public Health Bill which was now before Parliament and which sought to give to medical officers of health greater security of tenure of office would soon be placed upon the Statute Book.

Death of Gwilym Evans, L.R.C.P. & S. Edin., L.F.P.S. Glasg.

Mr. Gwilym Evans died at his residence, Blaengarw, Bridgend, Glamorganshire, on July 8th, after a short illness, in his forty-third year. The deceased, who received his medical education at St. Bartholomew's Hospital and Glasgow, took the L R.C.P., L.R.C.S. Edin., and L.F.P.S. Glasg. in 1888, and shortly afterwards commenced practice at Blaengarw. He was for the past 16 years surgeon to the Ocean Collieries. He was very popular and was highly esteemed for his generosity to the poor. He took a great interest in educational matters and was for some time chairman of the Ogmore and Garw school board. He leaves a widow with whom much sympathy is felt. The funeral took place on July 11th at Nantymoel, where Mr. Evans was born, and was largely attended.

July 17th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

School of Medicine of the Royal Colleges, Edinburgh.

At a meeting of the governing board of the School of Medicine of the Royal Colleges, Edinburgh, the secretary and registrar, Mr. R. N. Ramsay, reported that the number of students attending the school during the winter session 1905–06 was 1284 and during the summer session 1906 the number was 996.

St. Andrew's Ambulance Association.

The annual meeting of this association was held last week in Glasgow, the Marquis of Breadalbane, president of the association, being in the chair. The twenty-third annual report, which was read at the meeting, shows that during the past year in Glasgow alone the number of calls has been 4396. Out of the total 2708 were cases of accident, while 1688 were cases of illness. In 176 cases the wagons were not required on arrival. Of the 2708 calls to accidents, 866 were from police offices, houses, and stairs; 929 were street accidents, 352 were from public works, 230 from docks and wharves, and 155 from railways and stations. The Royal Infirmary, the Western Infirmary, the Victoria Infirmary, and the Maternity Hospital received 3624 of the total number of cases, the remainder being taken to their homes or other institutions. Owing to the generosity of two Glasgow gentlemen the council of the association has been able to place with the Argyll Motor Company, Limited, an order for a four-cylinder 16–20 h.p. motor ambulance wagon for use in the Glasgow area. This will necessitate increased expense in the upkeep and an appeal has been made to the public for more support.

Dumfries Hospital Dispute.

In connexion with the erection of the new hospital for infectious diseases to be built near Dumfries there has been a good deal of friction between the various parties concerned. The burghs of Dumfries and Maxwelltown some time ago agreed to combine in the erection of a fever hospital. The Dumfries council selected a piece of ground on its own property at Castledykes as the site, and secured the approval of the Local Government Board. Maxwelltown then objected to the situation, being close to Dumfries sewage works, and they were supported in their objections by Dr. J. Maxwell Ross, medical officer of the burgh. A public meeting of the ratepayers of Dumfries was next held, when the site was unanimously condemned and the council was requested to look out for a new site altogether. Finally the town council met and decided to ignore the finding of the public meeting. Last week, however, the town clerk of Dumfries received a letter from the Local Government Board suggesting to the council that it should seek a new site.

Caledonian Medical Society.

The twenty-sixth annual meeting of this society was held last week in Stirling public hall under the presidency of Dr. W. A. Mackintosh of Stirling. There was a representative attendance from both sides of the Border. In his presidential address Dr. Mackintosh dealt with the present position and prospects of the Gaelic language. He referred to the apathy of the Gaels in Scotland in regard to the matter and showed that the only way to prevent the language from entirely dying out was by systematic teaching in the schools. The Scottish Education Department had done a great deal in providing opportunities for learning Gaelic and he hoped that advantage would be taken of these. In the evening the annual dinner of the society was held in the Golden Lion Hotel.

Aberdeen Public Health Committee.

A meeting of the public health committee of the Aberdeen town council was held on July 11th. Letters were read from the British Women's Temperance Association requesting that several copies of circulars and posters issued by the association should be circulated throughout the city bearing the signatures of the Lord Provost, the town clerk, and the medical officer of health. Councillor Kemp spoke strongly in favour of this being done. Councillor Dunn also supported the proposal but the committee could not see its way to grant the application and it was ultimately decided to request the medical officer of health to prepare a circular pointing out the detrimental effects on the health of the citizens of the excessive use of alcohol and to submit the circular to a future meeting of the committee. It was agreed to give effect to a request put forward by the Local Government Board to draw up a circular, to be circulated by medical practitioners and others, with reference to the feeding and treatment of infants by their parents. The sanitary inspector was instructed to appoint two female health visitors in place of the one retired at a salary of £65 or £70 per annum. The committee visited the City Hospital and found everything in good order.

Quatercentenary of the University of Aberdeen.

The subcommittee consisting of the conveners of the several committees having charge of the arrangements in connexion with the celebrations has adopted the following programme subject to the approval of the general committee:—

Tuesday, Sept. 25th.—10 30 A.M.: Service in the chapel at King's College. 2.15 P.M.: Procession to the Strathcona Hall (the temporary hall which is to be erected on the vacant ground in Gallowgate for the accommodation of from 4000 to 5000 persons) 3.30 P.M.: Presentation of the addresses from other Universities and from learned societies in the Strathcona Hall. 8 P.M.: Town council banquet in the Music Hall 8 P.M.: Students' torchlight procession.

Wednesday, Sept. 26th.—11 A.M.: Conferring of degrees in the Mitchell Hall. 2 P.M.: Sports at King's College. 3 P.M.: Reception by the University at King's College. 8 P.M.: Students' ball in the Music Hall. 9.30 P.M.: Reception in the Art Gallery.

Thursday, Sept. 27th.—1 P.M.: Arrival of the King at Marischal College and opening of the new University buildings by His Majesty. 8 P.M.: The Chancellor's dinner in the Strathcona Hall. 9 P.M.: Town council's fireworks display.

Friday, Sept. 28th.—Excursions in the city and neighbourhood in the early part of the day. 9 P.M.: "At home" at Marischal College 10 P.M.: Students' symposium in the Strathcona Hall.

Aberdeen Lunacy Board.

At a meeting on July 10th the chairman said it was gratifying to see that the estimate, compared with last year, for the upkeep of the asylum buildings and plant was lower by £250. It seemed to him that there had been good management on the part of Dr. C. Angus, the medical superintendent, and Mr. Peters, the steward. During the past year they had maintained 419 patients at £10,517. The estimate for 436 patients for the current year was £10 700—£1130 less than the amount paid in 1903 and £1456 less than in 1904 The amount to be raised by assessment for the providing account was £9519, a less sum compared with last year's accounts. The reduction of the tax would in consequence amount to from one farthing to three-eighths of a penny in the pound. He was sorry that Dr. Angus was not with them that night and they hoped he would have a speedy recovery. Dr. Angus deserved their best thanks for his services at the asylum. Referring to the Banff Asylum, the chairman said that in 1868–69—when the buildings were new—the cost for maintenance and providing per patient was £37 13s. 8d.; in 1903–04 the providing account was reduced to £5 12s. 3d., the net cost of both maintenance and providing being £27 8s. 10d. That showed that as time went on there was a tendency, with good management, to reduce the cost of the maintenance of lunatics.

July 17th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Irish Medical Association.

THE committee of council of the Irish Medical Association held a meeting at the Royal College of Surgeons on July 10th. Seven new members were elected and the following motion was carried:—

> The committee of council strongly urge upon the secretaries of the county branches the necessity to have inserted in the local newspapers extracts from the "Journal" relating to the unions in which the salaries of medical officers have been revised, and all other matter which would seem to improve the condition of the dispensary medical officers.

The Tinned Meat Scare.

The public analyst of Belfast has reported to the public health committee that during the quarter ended June 30th 491 samples have been sent for analysis, a much larger number than can be done carefully and skilfully by one person, and he asks that if the number be continued either an assistant should be paid by the corporation or that allowance should be made for the payment of one. Some of the samples received, such as corned beef, cooked beef, tinned salmon, chicken and veal, &c., are subjects for a skilled bacteriologist, as chemical analysis can do little beyond indicating the presence of preservatives or colouring matter.

Irish Food Factories.

In the annual report of the Chief Inspector of Factories and Workshops for 1905, which has just been published as a Blue-book, there are some startling disclosures relative to the conditions under which workers are employed and the manner in which food products are dealt with. It is reported how little attention is paid to cleanliness in the majority of food-producing places. The bottle-washing rooms, in which empty jam-pots from which it is desirable to remove the dirt and old labels are washed, are not only unsatisfactory from the point of view of the workers in them but would probably very disagreeably impress the customers. The jam, confectionery, biscuit, condensed milk, and margarine factories in Ireland present an alarming state of affairs. The personal cleanliness of the workers is animadverted upon and it is said the matter of cleanliness has received scant attention in many of the Irish factories. The statements made by the inspectors in this Blue-book with reference to the conditions under which work is carried on in Irish food factories are of a very startling and distressing character and they indicate a state of matters which should be remedied at once if the industries referred to in the report are to make any real progress. Altogether, the facts disclosed, if proved, are of a very damaging character and must be dealt with without any delay. The Chicago scare has probably drawn attention to the matter.

County Antrim Infirmary.

From the annual report of the County Antrim Infirmary, just issued, it appears that during the past year 338 intern and 509 extern patients were treated (an increase of 18 of the former and a decrease of 42 of the latter as compared with the previous year). There were 293 accident cases—217 extern and 76 in the hospital, and there were 118 operations. Financially there is a deficiency in the year's working, the expenditure having considerably exceeded the income. The annual expenditure on each patient for drugs and dressings was £4 17s. 7d. and for food £11 12s 10d.

Post-Graduate Lectures in Belfast.

The course of post graduate demonstrations and lectures given by the staff of the Royal Victoria Hospital began on July 16th and a large class is in attendance.

July 17th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Writing of Scholars.

AT a meeting of the Society of Public Medicine and Hygiene held on June 27th M. Desnoyers read a paper on the above-mentioned subject. He is strongly in favour the sloped style of writing, holding that the upright style only practised by primitive peoples who have but little iting to do. It has also been noticed that sufferers from iters' cramp generally employ the upright style. Two ildren were made to write before the meeting. They were ipped to the waist and although they wrote in the sloping le they kept the upper part of their bodies perfectly aight. M. Desnoyers wished that the authorities should struct schoolmasters to train their scholars in writing so as avoid the risks caused by the bad position of the scholar ilst writing. M. Javal, who some years ago published a ok dealing with the question, did not think that upright iting produced all the evils which were attributed to it. his opinion it was quite natural that a child who began to arn to write by copying should make his first letters right. Later, when he was anxious to write more rapidly, began to slope his writing. M Desnoyers replied that thought it better for a child not to learn two different nds of writing but that he should begin as he meant to ntinue.

Mycetoma of the Dorsum of the Foot simulating Sarcoma.

At a meeting of the Surgical Society held on June 7th a per was communicated by Dr Braukt of Algiers on the llowing case. An Arab, aged 57 years, had a tumour on e dorsum of his foot. The growth was nearly of the size the fist, its consistence, though it varied from time to ne, was generally hard, and it was painless. The tumour as removed and microscopical examination showed that it as a mycetoma. The points of interest in the case were:) the circumscribed form of a tumour which is generally ffused; (2) the fact that it occurred on the dorsum of the ot, whereas mycetoma is almost always on the plantar pect; and (3) the fact that the bones of the foot were ite unaffected, contrary to what is generally found.

Malposition of a United Fracture.

At a meeting of the Surgical Society held on July 4th . Chaput read an account of a case in which there had en a fracture of both bones of the leg and the bones had ited in a vicious position Radiography showed that the acture lay some two fingers' breadth above the lower interticular line. The two fragments of the fibula formed an gle open outwardly, while the upper fragment of the tibia d slid over the internal aspect of the lower fragment. M. aput corrected the deformity by resecting from the tibia conical fragment with its base internal and from the fibula small cylinder of bone. After this reduction was easy and e patient recovered with a straight, useful limb. In the scussion which followed M. Chaput's treatment met with e approval of the meeting.

Saline Baths in the Treatment of Suppurative Tuberculous Arthritis.

At the same meeting of the same society M. Reynier owed a patient on whom he had performed resection of e elbow-joint for suppurative tuberculous arthritis with open wound. Profuse secondary suppuration followed e operation and with the view of curing this M. Reynier nployed saline baths and dressings soaked in saline water. wo arm baths were given per diem lasting for three hours ach. Five or six litres of hot water were used containing rom 50 to 60 grammes of mother liquor from Salies. On he conclusion of the bath the arm was dressed with comesses soaked in a similar solution. This treatment was apidly successful and M. Reynier said that he could not ecommend it too highly as an alternative to resection in hose cases of suppurative tuberculous arthritis where there as an open wound. More especially would he use it in the ase of the elbow-joint resection of which was a grave operaion. M. Quénu took exception to this last remark and did ot consider resection of the elbow joint particularly serious he post-operative suppuration was generally of a mild haracter and the results of the operation were excellent.

French Sanatorium Medical Officers.

There has just been founded at Paris a Society of the Medical fficers of French Sanatoriums. The object of the society s the scientific discussion of tuberculosis with special regard o the working of sanatoriums both public and private. The ociety, which consists of active members only, is open to all anatorium medical officers, whether principal medical officers r assistants. The administrative body is a committee comosed of five members, and the President is Dr. Calmette. Three meetings will be held per annum, two in Paris and the third at some provincial sanatorium.

The Academy of Medicine.

M. Ferdinand Widal was elected a titular member of the Academy of Medicine on July 3rd, in the section of Hygiene and of Legal Medicine, by 67 votes out of 76.

The Old School of Medicine.

In conformity with the report of M. Grébauval, the Municipal Council of Paris has decided to authorise the Prefect of the Seine to grant a 99 years lease to the General Association of Students of the building in the Rue de la Boucherie which was formerly occupied by the School of Medicine. A yearly rent of 3000 francs is to be paid by the association. The association also undertakes to restore those portions of the building which are of historical interest.

Compliments to Professor Pozzi.

On Sunday, July 8th, the friends of Professor Pozzi presented him with a medallion, a true work of art by Chaplain, and a special copy (*livre d'or*) of a book containing unpublished articles upon questions of surgical gynæcology. The ceremony took place in the theatre of the Pasteur annexe of the Broca Hospital. Dr. Debove, Dean of the Faculty of Medicine, presided and made the first speech. He was followed by Professor Renaut of Lyons, Dr. Dartigues, head of the clinique at the Broca Hospital, Dr. Jayle, the secretary of the committee, and Dr. Monprofit. Professor Pozzi then rose, and having thanked M. Clémenceau, the Minister of the Interior, who was present at the ceremony, he reminded his audience of the fact that M. Clémenceau, who is a Doctor of Medicine, had himself obtained a gold medal from the faculty. He then referred to the history of the chair of gynæcology and conveyed his thanks to his pupils and all those who had been associated with him in the work of this chair. Dr. Debove then presented Professor Pozzi with the medallion amidst loud applause.

The Responsibility of the State for Hygienic Deficiencies in Government Offices.

The Conseil d'État has just given a most important judgment with regard to the responsibility of the State in the matter of hygiene. A post-office official who had arrived at Bastia in perfect health developed in a few years symptoms of tuberculosis and died in 1903 from tuberculous bronchitis. His widow demanded a pension. She was refused as her late husband had not reached the age limit necessary for a pension by law. The widow therefore appealed to the Conseil d Etat, saying that her late husband had been placed in an unhealthy office where he was constantly in contact with a tuberculous clerk and that two clerks who had worked in the same office before him had both died from tuberculosis. She quoted the law which gives widows of those who die from grave accidents incurred in the performance of their duties a pension, and she argued that a disease arising from definite circumstances connected with abnormal conditions in the service should be considered as a serious accident. The Conseil d'Etat coincided in this view and the widow was awarded her pension.

July 17th.

ITALY.

(FROM OUR OWN CORRESPONDENT.)

"*Flagrantis atrox hora Caniculæ.*"

WE are nearing the dog-days. Sojourners from the British Isles—all, in fact whose constitutions are built on northern lines—have hastened to put the Alps, or the "watershed," as the Americans call them, between themselves and the Italian sun. Not that there are not shady nooks at high altitudes even in Central Italy where the great heat may be avoided. The "Tuscan Switzerland," as that special chain, or rather network, of the Apennines is called, abounds in such places of refuge. Take, for example, Camaiore in the province of Lucca. "There," as a correspondent of British nationality tells me, "you are surrounded by quite imposing mountain peaks which, so near the Mediterranean, have as grand an appearance as the Swiss Alps. We can, and generally do, spend the whole day out of doors and feel greatly invigorated by the change. It seems impossible that we are only one and a half hours' drive from that Sahara Viareggio! It blows a keen, cool N.W. or S.W. wind every day from 9 A.M. till sunset, and the solar rays cannot pierce the dense umbrage of the ilex trees on the grassy terrace. We are not nearly so high as at Barga (the Della Robbia country above Bagni di Lucca) and yet we are always cool—even cold at times—while at Barga, from its being shut in by mountain walls, the heat is often stifling. Looking through the screen of cypresses and across the valley I see a grey old church-tower whose silvery bells fall pleasantly on the ear at matins and at Ave Maria, as their tones come wafted from the mountain opposite—quite conducive to quiet work or 'studious musing,' till it is time to seek repose in the spacious dormitory with its windows all night wide open." All the same, while once in a way such a resort is for British subjects a delightful escape from the sultry lowlands, it is not bracing enough if repeated from year to year. Many an English-speaking family, after spending the summer annually at Vallombrosa, for instance, have found that something more than cool shade at 3000 feet above sea-level is required if you would avert premature break-down. Climatic change is necessary for such constitutions—in proof of which we have the testimony of British residents in Italy who, summer after summer, have made their *villeggiatura* at Airolo on the Italian side of the St. Gothard tunnel and yet felt their vigour deteriorating till they bethought them of trying Göschenen, on the Swiss side, when they immediately felt they had "changed for the better." Meanwhile, the approach of the dog-days has inspired a stampede from all the chief Italian cities, especially from the capital and from its sultriest quarter, the Vatican, whence the *pezzi grossi* or leading functionaries, have already gone to seashore or hillside as a welcome escape from daily service in the Cappella del Coro, with its monotonous chanting, or from the various offices, open as they are for two or, at most, three hours per diem and not all the week through. The Cardinal Secretary of State starts for Castel Gandolfo, on the Alban hills, leaving the Holy Father to face the heat in the Apostolic Palace, some 2000 feet lower on the least healthy of Roman hills. His Holiness continues to give audiences, but to very few at a time, his health, though somewhat improved, indicating need of rest and relaxation from official cares. He has resumed his daily promenades in the Vatican demesne but while in the first few months of his pontificate he would take long walks on foot in the well-shaded alleys he has now to resort to his carriage, whence he alights for a little to converse with the more intimate of his suite but returns to it not unwillingly after covering a few hundred yards. "Happy you," he said the other day, "who can go where you like. Go, go, and get as well as possible. When you come back you will certainly find me here."

"*L'Insidie alla Vita.*"

"Life's Enemies in Ambuscade," as the above may be rendered, is the title of a very scientific, very attractively written, and very opportune volume, addressed to Italian heads of families and to the educated people of Italy in general. Its lady writer is Dr. Teresita Ruata, assistant to the professor of materia medica in the University of Perugia, on whose medical staff her father has long held a distinguished position, apart from his extra-professorial work in literature, particularly on public health. Miss Ruata sums up the most recent and most scientifically accredited findings of pathological and clinical medicine and brings them home to the appreciation of the lay reader with a clearness of exposition and occasionally with a dramatic force that never fail to satisfy and to sustain the interest which it evokes. Italian literature comprises no better account in such brief space of, for instance, the "opera benefica" of Lord Lister or of the prophylaxis or treatment (if not of the etiology) of malaria associated with the names of Manson and Ross. After the "insidie" of life Miss Ruata proceeds to enumerate the processes and the means of "alimentazione" and illustrates the disastrous results of their systematic or even occasional infringement by such retributive visitations as, for instance, pellagra, on which she gives succinct but quite sufficient and impressive information. The book,[1] with its pictorial illustrations as a help to the letterpress, is not bulky and well deserves perusal on the part of English-speaking residents in Italy, for whom it has recommendations and warnings hardly less opportune than for the Italian public to whom it is primarily addressed.

July 15th.

EGYPT.

(FROM OUR OWN CORRESPONDENT.)

Prevention of Cholera.

THE Public Health Department has now published in book form a collection of decrees and regulations which have been issued during the last ten years as a useful guide to those in charge of measures which will be taken against the spread of any future outbreak of cholera. It is hoped that the book will be carefully studied by all public health inspectors in the country districts, so that they may be aware what measures can be taken promptly and without confusion. It is, of course, not intended to discourage initiative but rather to point out the lines upon which previous experience has shown that the most satisfactory results can be obtained. The great success which Egypt has attained in the stamping out of epidemics of both cholera and plague during recent years is due to the fact that when the country is declared to be infected stringent laws at once come into force which could not be submitted to in normal circumstances. For instance, in large towns when cholera has been declared all fairs are prohibited, insanitary dwellings are whitewashed inside (the Egyptian, unless controlled, prefers to whitewash the outside only of the house), street sweepings are burned outside the town instead of being preserved for heating the public baths, medicines for diarrhœa are distributed free, cesspools are emptied and disinfected, while the latrines of mosques or other buildings which are considered dangerous to public health may be closed, and a portion of the cemetery is chosen for the burial of those who have died from cholera and is used exclusively for this purpose. But the most important regulation refers to the prevention of pollution of the water-supply; local regulations regarding the mooring of boats, drawing of water, washing of clothes, and watering of animals must be strictly enforced by the police, while frequent inspections must be made and special attention paid to mineral water and beer factories. Stables and cow-sheds in an insanitary condition may be temporarily closed if they are considered dangerous to public health. In order to encourage the drinking of pure water stand-pipes should be erected in various parts of any town which possesses a water-supply laid on by pipes, while arrangements should be made with the water companies to keep their workmen on the premises, they should not be allowed to walk about the town, and should be inspected daily by a responsible person before going to their work. Every water-carrier should be obliged to bring his goat-skins or water-cart to be disinfected, the former by 2 per cent. sulphuric acid and the latter by steam; every skin and cart should be stamped after disinfection and no one should be allowed to fill a skin or cart at the stand-pipes unless it bears the Government stamp. All schools may be closed, as also public baths, drinking fountains, and the ablution tanks of mosques. The various regulations are drawn up in a simple and practical way and are supposed to be carried out by the local sanitary commission, but it is needless to say that all success will depend upon the constant presence of the English inspectors of public health. Great stress is laid upon the importance of early recognition of the disease and the headmen of villages are to be informed that suspicious cases of sickness should be at once removed to some temporary shelter outside the village without waiting for the arrival of the public health officials. This is almost too much to expect from sheikhs who cannot see the importance of keeping their water-supply free from the contamination of human excrement, but in another generation education will work wonders. It is quite a mistake to suppose that any Egyptian prefers to drink polluted water, though he is quite content to do so if no pure supply is at hand. In order to obtain specimens for bacteriological examination, which is all-important in the early diagnosis of imported cholera, boxes containing a corked test tube with wire and cotton-wool are supplied by the Central Administration and as it often happens that the earliest cases of cholera are not seen until after death the sterilised cotton-wool should be introduced into the rectum of the suspicious case, and after having been allowed to absorb sufficient discharge it should be placed in the sterilised test-tube and forwarded immediately to the Government bacteriologist. Necropsies are only permitted in very exceptional cases. Among sonal precautions the officials are warned to pay special ention to the necessity of carrying a supply of boiled nking-water for themselves and to be provided with a ution of corrosive sublimate for washing their hands. It difficult to over-estimate the importance of isolating sick when undoubted cases of cholera have occurred. e patient, if alive, should be removed to hospital while house and all people who have been in contact with him ust be disinfected, while if the patient is already dead body must be washed with corrosive sublimate and ried in the special quarter of the cemetery in a shroud aked in sublimate solution. Cases are allowed to be ated in their own houses provided isolation can be iciently maintained. Special instructions are issued with gard to the disinfection of clothing, drinking vessels, and ells, and rules for nurses, railway officials, and river police e laid down.

Bacteriological Report from the Tor Quarantine Camp.

Dr. F. Gotschlich has now issued his annual report hich confirms last year's report in one interesting way. s in 1905, there was a complete absence of cholera among e pilgrims returning from the Holy Places, but again two cases the comma bacillus was found. He examined e fæces of 127 pilgrims in hospital for various kinds disease and in 18 vibrios were found, always from ases of dysentery or colitis and never in a single stance from an individual whose intestines were normal. nly two of the 18 cases, however, gave a specific reaction ith cholera serum obtained from Berlin at a dilution of in 2000; the other 16 cases gave no reaction at all, even ith a dilution so strong as 1 in 50. This year's bacillus lso gave a perfect serum reaction with those found at Tor ast year. The two suspicious pilgrims came from Asia and ere neither of them natives of Egypt. It has long been nown that various epidemics of cholera have been associated with comma bacilli which do not correspond in every etail with Koch's bacillus, and it is evident, as Metchnikoff as stated, that the cholera vibrio is one of the most pleomorphic of all organisms. Dr. Crendiropoulo, the director f the quarantine laboratory in Alexandria, has just ublished an interesting report on the subject of the ifferential diagnosis of vibrios. He concludes by expressing his belief that in order to classify a vibrio very biological test must be applied, for agglutination and Pfeiffer's reaction by themselves are not enough for dentification. His paper is based on the examination of 42 cases, mostly choleraic or dysenteric, obtained from India, Egypt, and Europe. Only 18 of the 42 bacilli were agglutinated by an undoubted cholera serum. Dr. Zirolia, director of the quarantine laboratory at Port Said, has also reported on six vibrios isolated from the water-supply of ships. He examined altogether 384 samples and found vibrios in water from 82 ships but in only six was there a positive agglutination with the Berlin cholera serum. All these six vibrios were pathogenic to guinea-pigs but not to pigeons. These workers have been greatly stimulated by the encouragement of their chief, Dr. M. Armand Ruffer.

July 12th.

NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Death of Dr. Mary Putnam Jacobi.

THE profession of medicine in this country has lost a prominent member in Dr. Mary Putnam Jacobi whose death has just been announced. The late Mary Putnam was born in London, England, on August 31st, 1842, and was a daughter of George P. Putnam, a well-known New York publisher. She studied medicine at the Woman's College, Philadelphia, the New York College of Pharmacy, and the École de Médecine in Paris where she had the honour of being the first woman admitted to medical classes. She graduated in Paris in 1871 and in 1873 married Dr. Abraham Jacobi, the distinguished New York physician. She was the first woman member of the New York Academy of Medicine and served for 12 years as a dispensary physician to Mount Sinai Hospital. For ten years she was a professor in the Woman's Medical College, and subsequently for three years a professor in the New York Post-Graduate School of Medicine. Her essay on "The Question of Rest for Women during Menstruation" won the Boylston prize at Harvard University, Boston, Massachusetts. She was, indeed, an author of recognised ability and some of her works were: "The Value of Life," "Cold Pack and Massage in Anæmia," "Hysteria," "Brain Tumours," "Studies in Primary Education," and "Common Sense Applied to Woman Suffrage." These and multiple essays and articles in the medical and lay press made her an author of more than national repute.

Yellow Fever.

Several cases of yellow fever are reported at Ship Island, the quarantine station of the coast of Mississippi in the Gulf of Mexico. They were on the s.s. *Whitehall*, from Colon, isthmus of Panama. The steamer had taken a cargo of lumber there. Colon is a foul and pestilential spot. Yellow fever has been endemic there for many decades. The news regarding these cases developed as the result of an inquiry by President Irion, of the State Board of Health, Louisiana, sent recently to Dr. Hunter, State health officer of Mississippi. In reply to President Irion Dr. Hunter said that he had no knowledge of any cases but would make due inquiry. Later he telegraphed to President Irion as already set forth. It is known here that several cases of yellow fever have occurred in that ancient hot-bed of the disease, the city of Havana. The results of the reports made by the commission sent by the *New York Herald* to Cuba, 1904 and 1905, have been the very unusual and energetic action in cleaning the city of Havana, with its foul *patios*, or court yards. With an increase of high summer temperature in the Southern United States the student of yellow fever will expect new cases, or the usual echo after a year of an epidemic such as visited New Orleans and its vicinity last year.

The Insurance Scandals.

Dr. Walter R. Gillette, a former medical director of the Mutual Life Insurance Company of this city, and, until recently one of its vice-presidents, has just been indicted by the Grand Jury. Six counts were alleged against him for perjury and forgery. He will be tried in September next with his fellow vice-president, Mr. Robert A. Granniss. Dr. Gillette is a Fellow of the New York Academy of Medicine and physician to several hospitals.

July 10th.

NOTES FROM INDIA.

(FROM OUR SPECIAL CORRESPONDENT.)

The Board of Scientific Advice.

THE Board of Scientific Advice, established in 1902 under the enlightened rule of Lord Curzon, has already attained considerable reputation for scientific investigations. Its reports are communicated to the Royal Society, which by an advisory committee furnishes the board (here in India) and the Government with suggestions. A recommendation is made to the Government of India to increase the superior staff of the Geological Department partly for the purpose of additional surveys and partly for economic investigations. Another line of investigation is in the botanical exploration of areas not yet investigated, and more especially for providing separate floras of the various provinces. The board further recommends that the physiological investigations into the nature and cause of lathyrism should be continued. Other investigations, contemplated refer to the movements of glaciers, the discharge of silt from Indian rivers, experiments for the improvement of cotton, and experiments in growing flax.

Opportunities for Medical Research.

Some very admirable suggestions for facilitating research works have recently been put forward by the sanitary commissioner with the Government of India, but unfortunately the Government puts difficulties in the way of officers willing to take advantage of the laboratories either for instruction or for original investigations. Colonel Leslie refers to the want of officers sufficiently skilled to carry out investigations regarding malaria, kala-azar, Delhi boil, and more particularly dysentery and suggests that a limited number should be deputed to the laboratories. The Government accepts the proposals for certain officers of the Indian Medical Service, but the application of an officer has first to be backed by the sanitary commissioner, then it has to be submitted to the Director-General, and then to the local government (to decide when the officer in question can be spared from his ordinary duties). No deputation allowance will be given and the officer will lose any allowances which he receives for local duties. This is poor encouragement to individual officers and the further pronouncement of Government that no addition to the sanctioned strength of the Indian Medical Service is contemplated on account of officers studying at a laboratory shows the indifference which exists to the higher study of Indian diseases. This is shortsighted policy and Indian civilians have yet to learn that it is only by scientific medical research that even the expenses of jails, asylums, and other public institutions will be reduced, to say nothing of the lessened mortality and the better treatment of disease.

The Plague Epidemic.

The plague epidemic has subsided to such comparatively small proportions that the mortality excites but little interest Only 7660 deaths were recorded for the whole of India during the week ending May 26th. In Eastern Persia, however, the disease continues and shows no sign of abatement and the announcement has this week been made that Jeddah is an infected port and that the plague regulations will be enforced against vessels arriving from that port Statistics covering the period since plague was first reported in 1896 give the following yearly records of mortality.

1896	1,701 deaths.	1901	273 679 deaths.
1897	56,055 "	1902	577,427 "
1898	118,053 "	1903	851,263 "
1899	133,789 "	1904	1,022,299 "
1900	93,150 "	1905	950,863 "

In the present year about 170,000 deaths have been recorded up to the end of April, which gives a grand total of 3,729,000 since 1896. Even this is under the mark, and probably 5,000,000 would more correctly be the death roll. An experiment of considerable importance has recently been made to the effect that the ordinary disinfection by acid perchloride of mercury is ineffective against the rat flea Even a 1 in 500 solution fails to kill fleas except after prolonged immersion, but izal and analogous bodies are successful after short periods.

The Strike of Students at Lahore.

The strike of the Lahore medical students still continues and they have apparently had no reply to their representations. Some 35 out of 260 have returned to the college and have been readmitted. The latest move was a large public meeting, at which an executive committee was appointed for the purpose of laying their grievances before the Lieutenant-Governor. Their chief complaint seems to be against the menial work that they were compelled to do which they considered unnecessary and degrading. Their feelings have been hurt by their repeated representations on this and other matters not being attended to.

The Jails in Bengal.

The report on the jails of Bengal for the past year shows the average prison population of the province to have been 14,934 These were quartered in 35 principal jails and 67 subsidiary jails. The death-rate rose to 25·3 per 1000 from 19 5 of the previous year, which was the lowest on record. For 1904 the rate at Balasore was over 40 per 1000, but this year under a new superintendent it has fallen to 22 6. In four jails this year, however, the rate is over 40 per 1000: Burdwan at 43·3, due partly to floods which invaded the compound but chiefly to overcrowding; Purulia at 46·6 per 1000 where the main barracks are radically defective; Midnapore at 45 per 1000, which is always above the average; at this jail the prisoners are said to be always admitted in bad health, but serious defects in the barracks exist; and Charbassa, at 44·1 per 1000, but which has only a small prison population. The report shows the great prevalence of pulmonary tuberculosis in the province and the Inspector-General suggests utilising Berhampore jail for cases of pulmonary tuberculosis only. Overcrowding is reported in 16 jails. There seems to be great discontent among the warders as 1280 punishments were inflicted on them and 82 resigned. Deficient pay and illiberal rules regarding sick leave are the chief complaints.

The Water Scare in Calcutta.

The water scare in Calcutta has not been allayed by subsequent inspections of the three town reservoirs. Cracks in the masonry have been observed in all of them and percolation of subsoil and probably other foul waters is certain. The ensuing monsoon will test the matter more severely but it cannot be denied that at the present moment the water-supply of the whole city is liable to serious contamination. Like most places in India Madras has its difficulties and dangers in regard to the filtration of water. A new scheme is under discussion which is estimated to cost 35 lakhs, towards which the Government will assist with 14 lakhs. The balance will have to be met unfortunately by increasing the water tax and drainage tax to the maximum.

June 9th.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

The Plague.

A FRESH case of bubonic plague has been reported from Subiaco, a suburb of Perth, West Australia. The man was working in the centre of Perth. In Sydney no further cases have occurred. About 2300 rats are killed weekly and of these some 800 are carefully examined at the Board of Health laboratories. Since April 18th only one rat has been found to be infected with plague. It was taken in the block of buildings in Clarence- and Kent-streets, where the last cases of plague in the human subject occurred. A thorough search in the vicinity of the premises in Alexandria, where a patient who died from plague had lived, showed that the rats had fled—only a very few were caught and none was plague-infected. Some of the properties, however, were in an insanitary condition. Dr. J. Ashburton Thompson, President of the Board of Health of New South Wales, has received an invitation from the American Medical Association to visit Boston and to deliver an address on Plague. He is unable to attend but has forwarded an address. Dr. Thompson has always taken the view, based on the observations and experiments made in Sydney, that fleas were essential to the communication of plague from rats to man, a view confirmed by the Indian commission's experiments.

Report of the Board of Health of Victoria.

A rather belated document has been published by the Board of Health of Victoria. It is a report for seven years up to December, 1904. It is almost entirely statistical. It is stated that the need for federal action in connexion with quarantine and the prevention of the introduction of exotic disease has been frequently illustrated during the period under review, but nothing has been done except the holding of a conference in 1903 of representatives of the health authorities of the several States. A report was drawn up but no action was taken. The striking immunity which Victoria has had from plague is ascribed to the preventive measures adopted by the Board and the loyal coöperation of municipal and shipping authorities. The urgent need for extending activities in preventing tuberculosis is affirmed, especially by extensive improvements in the sanitary conditions of the poorer classes.

Pure Food.

Under the Pure Food Act of Victoria the Board of Health is empowered to make regulations for "securing the cleanliness, freedom from contamination, and adulteration of any article of food or drug, or other article, substance, or compound; and for securing the cleanliness of receptacles, places, and vehicles used for the manufacture, preparation, storage, packing, carriage, or delivery of any article of food or drug, or other article, substance, or compound." The following regulations have been made:—

> 1. No person who sells bread or meat, and no employee of such person, shall receive into any place or vehicle for the reception or storage of bread or meat for sale any bread or meat which has been returned after delivery at any house. 2. No person who sells bread or meat shall use or cause to be used as a material for casing, covering, enclosing, or packing bread or meat for carriage or for sale any second-hand paper or any newspaper, or part of a newspaper, or any paper or substance on which there is printing which can come into contact with the bread or meat.

And with regard to milk, cream, butter, cheese, cooked meats, bread, pastry, confectionery, honey, jam, and other articles of food to which flies are attracted and which are ordinarily consumed in the condition in which they are purchased—

> 1. Any person who sells on any retail premises (including cafés, restaurants, and licensed premises) any of the above-named articles of food in other than sealed packages shall, as far as practicable,

otect such articles of food from dust and flies by storage in covered ceptacles, or by means of metal covers or wire gauze screens, or her effectual appliance. 2. No person shall transport through the reet for sale any of the above-named articles of food, unless the me is properly protected from dust and flies. 3. Any person using y vehicle for the storage or exposure for sale in the street of any uit shall, unless the fruit is otherwise adequately protected from st, provide and fit to such vehicle close fitting screens on every side cept that from which the fruit is removed for sale.

he use of preservatives in food has also engaged the attenon of the Board which desires to place the public in a osition to know where they stand in regard to the articles f food which they consume. As the application of scientific ethods of manufacture becomes more general, it is regarded s indubitable that the use of foreign preservatives will be educed to a minimum. In the meantime, however, the Board has found it advisable to frame the following regulaions, which it is proposed shall be enforced on and after Dec. 31st the penalty for infraction being £10:—

1. To every article of food mixed with a preservative substance, and to very article of food mixed with any foreign colouring matter, or to ny wrapper or receptacle containing any such article so mixed, there hall be attached a label distinctly and legibly written or printed and etting forth (a) the nature and amount of such preservative subtance; and (b) the nature of any foreign colouring matter mixed with uch article of food. This regulation shall not apply to confectionery nor to the long used, well known condimental preservative substances—viz., common salt, sugar (sucrose or saccharose), spices, wood smoke, and vinegar; nor, as regards wine to the substances allowed under Section 25 of the Pure Food Act, 1905.

Provision is also made for the attachment of a label setting forth in a legible manner the quantity of preservative contained in every pound or pint of the article of food sold. It is further provided that the word "pure" must not be used to describe on the label any article of food not true to name, of standard composition, strength, purity, or quality, or which is mixed with any foreign substance.

Lunacy Reform in Victoria.

The Victorian Ministry has been considering the recommendations of the Inspector-General of the Insane, Dr. Jones, for improving the asylums. It has been decided to build a hospital for acute cases in the metropolitan district, providing for 125 patients, with a special staff. It is estimated to cost £30,000 to build. It was resolved to spend £9000 on reception houses at Ballarat, Warrnambool, and Sale, and in renovating the existing receiving house at Bendigo. All the existing county asylums are to be renovated. The present staff of untrained temporary attendants in the various asylums is to be replaced by a permanent trained staff who will begin as probationers. It was not finally decided whether any amending legislation should be introduced or what should be done with the new asylum.

Treatment of Inebriates.

The Chief Secretary of New South Wales has received a report from the Inspector-General of Charities and the Director of Labour as to the suitability of Rabbit and Milson Islands for the establishment of inebriates' homes. As has been previously mentioned, buildings for the purpose, costing £13,000, have been erected on Rabbit Island but not used. The report states that the islands form ideal situations for the proposed institutions and the land could be utilised for agricultural purposes, though the area on Rabbit Island is very small. It is considered impracticable to have two classes of patients, one paying and the other not.

Treatment of Epileptics.

The council of the epileptic colony in Victoria has had great difficulty in securing a suitable site, but the difficulty has been settled by the gift of some property at Clayton by Mr. J. Mason. It consists of 174 acres of particularly good land and the situation is regarded as very suitable.

Prevention of Tuberculosis.

A large and representative deputation waited on the Chief Secretary of New South Wales on May 23rd to urge that further precautions should be taken to prevent the spread of pulmonary tuberculosis. It was desired that notification should be enforced and more accommodation provided for patients in the advanced stages of the disease. The Minister gave a sympathetic reply and said that the matter would be considered by the Cabinet.

Sight and Hearing Tests on the Railways.

In accordance with the decisions of the Inter-State Conference of Railway Commissioners, held some time ago, new scientific tests for sight and hearing, uniform in standard, have been adopted in the railway service of the different States and the various employees have undergone examination by experts. In New South Wales the result has been that many men (30 per cent.) could not pass the tests and it was said that some of the best men were in consequence degraded and hardly treated. A deputation of 30 Members of Parliament waited on the Premier on May 17th to ask him to urge on the Commissioners the necessity of reverting to the old system of practical tests instead of Holmgren wools, acoumeters, and test-types. The Premier replied that he could not control the Commissioners but would place the views of the deputation before them. Subsequently, on May 28th, delegates from the Amalgamated Railway and Tramway Service Association interviewed the Railway Commissioners and asked for the abolition of the acoumeter test and the wool test; a modification of the card test; a proviso to the lantern test to enable an employee to appeal for a practical test; that sight and hearing tests should only apply to those connected with the safe working of trains; and that those who had already failed should have an opportunity of being re-tested under the modified conditions proposed by the association if adopted. Instances were given of a man who was absolutely colour blind being able to pass a wool test, and of another being able to pass a colour test without having any sense of comparison in the matching of the shades of a colour. The Commissioners agreed to abolish the acoumeter test and stated that orders would be given to substitute the voice test. They agreed, too, that sight and hearing tests should only apply to those connected with the safe working of trains, or to those likely to be promoted to positions connected with safe working. They also said that if modifications were decided upon opportunities would be given, on appeal, for re-testing under the modifications. The other proposals will receive consideration.

June 3rd.

Medical News.

UNIVERSITY OF LONDON.—At examinations held recently the following candidates were successful:—

M.S.—Thomas Percy Legg, King's College and St. Bartholomew's Hospital; William Paynter Neall, Royal Infirmary, Manchester, and London Hospital; and William Gordon Taylor, B.Sc., Middlesex Hospital.

D.Sc.—Alfred Walter Sykes, M.D., B.S., St. Thomas's Hospital, University of Marburg, and Laboratories of Examination Hall and Queen Charlotte's Hospital.

UNIVERSITY OF BIRMINGHAM: FACULTY OF MEDICINE.—The following is a list of the successful candidates at examinations held in June:—

I. Degree of Doctor of Medicine.—Thomas Webb Fowler, Robert Beeston Dennis Bird, and Alfred Ernest Remmett Weaver.

II. Degree of Master of Surgery.—(a) Official: Frank Marsh. (b) Under Ordinary Regulations: Class I.: Alex. Wathen Nuthall.

III. Degrees of Bachelor of Medicine and Bachelor of Surgery.—(a) Past Students of Birmingham Medical School.—Class II.: Frank Newstead Deakin and Charles Henry Maskew. (b) Under Ordinary Regulations.—Class II.: Reginald Hudson Astbury, John Staines Austin, Arthur Cecil Hircks, Claude Johnson, Harold Bruce Jones, and Walter Rowland Southall Roberts.

IV. Fourth Examination for the Degrees of M.B., Ch.B. Class I.: James Fenton, Arthur Addison Sanders, and Francis Brett Young. Class II.: Edward James Boome, Henry Neville Crowe, Eric Thomas Gaunt, John Kennedy Gaunt, Philip James Mason, Nevill Coghill Penrose, Arthur John Smith, Rupert Wesley Thompson, and Norman Valentine Williams.

V. Third Examination for the Degrees of M.B., Ch.B.—Part I.: Pathology and Bacteriology.—Class II.: John Adams, Charlotte Bailey, John Dale, George Henry Chavasse Mold, David Priestley Smith, and Edward Vernon Whitby. *Part II.: Materia Medica and Pharmacy.*—Class I.: John Adams, John Dale, Harvey Atkins Evans, and Edward Vernon Whitby. Class II.: Charlotte Bailey.

VI. Second Examination for the Degrees of M.B., Ch.B. Class II.: Walter Charles Blackham, Norman Alexander Bissell, Harold Gordon Browning, Humphrey Francis Humphreys, Violet Maud McCready, Cranston Walker, and Kenneth Douglas Wilkinson. Passed in part of the examination: James Henry Bampton (anatomy and comparative anatomy), John Selwyn Edwards (anatomy and physiology), Carl Euclid Molino (anatomy and physiology), Ethel Annie Wellman (anatomy and physiology), Harold Arthur Whitcombe (anatomy and physiology), and Henry Wilks (anatomy and comparative anatomy).

VII. First Examination for the Degrees of M.B., Ch.B.—Class II.: Eric Walter Assinder, Oscar Madeley Holden, Elizabeth Stephens Imrey, Lionel Gilbert Jordan, Ronald Douglas Nelson, and Henry Richmond.

VIII. Degree of Bachelor of Dental Surgery.—Class I.: William Bowater.

UNIVERSITY OF LEEDS.—At a Congregation of the University which was held at the medical school buildings on July 13th *Professor Smithells*, as Pro-Vice-Chancellor, conferred the degrees of Bachelor of Medicine and Bachelor of Surgery on the following candidates who had passed the recent examination:—

F. G. Dobson, E. R. Flint, S. R. Gloyne, J. J. Hummel, and F. E. Kendall.

The following pass lists are issued:—

Second M.B. and Ch.B. Examination.—Part I.: W. H. Brown and J. B. T. Keswick. Part II.: C. S. Brown, J. P. Musson, A. Riley, C. G. K. Sharpe, W. Shaw, R. E. Smith, and J. N. L. Thoseby.
Final M.B. and Ch.B. Examination.—Part I.: W. L. Dibb

ROYAL COLLEGE OF SURGEONS IN IRELAND.—*The following prizes were awarded for the summer session.* Barker anatomical prize (£31 10*s.*): P. G. M. Elvery. Carmichael scholarship (£15): C. Greer. Gold and silver medals in operative surgery: gold, D. Adams; silver: R. M. Bronte. Stoney memorial gold medal in anatomy. G. S. Levis. Practical histology: R. Adams, first prize (£2) and medal; and O. W. J. Wynne, second prize (£1) and certificate. Practical chemistry: J. J. Lyons and P. I. Wigeder (equal), first prize (£2) and medal. Public health and forensic medicine: T. O. Boyd and C. T. Callimore (equal), first prize (£2) and medal. Materia medica: J. J. Lyons, first prize (£2) and medal; and H. W. White, second prize (£1) and certificate. Biology: H. D. Gasteen, first prize (£2) and medal; and J. S. Pegum, second prize (£1) and certificate. The lectures of the winter session will commence on Monday, Oct. 15th.—The Barker Anatomical Prize for 1907, of the value of £21, is offered for competition and is open to any student whose name is on the anatomical class list of any school in the United Kingdom. The preparations entered must be placed in charge of the curator on or before April 30th, 1907. The prize is offered for a dissection showing the viscera in relation with the abdominal surface of the diaphragm. The relations of the common bile-duct, which should be seen opened up along its entire length, are to be retained fully. The conditions under which the competition is to be carried out are as follows:—1. The preparation must be sent to the Curator of the Museum of the Royal College of Surgeons in Ireland, each being marked with a fictitious signature and accompanied by a sealed envelope bearing outside the same signature, and containing within, (*a*) the full name of the competitor, and (*b*) a declaration to the effect that the work of the preparation has been carried out by himself. The printed form necessary for this declaration can be obtained on application to the Curator. 2. The dissections are to be mounted in vessels fitted with glass covers, but the covers must not be sealed down. Earthenware basins and plaster-of-Paris settings are not compulsory if the specimens can be better displayed and preserved by other means. 3. No prize will be awarded unless sufficient merit be shown, 70 per cent. of the total marks being the minimum. The following is the scale of marks: (*a*) for the merit of dissection, 60; (*b*) for excellence of setting, 20; and (*c*) for originality, 20—total, 100. Those dissections for which prizes are awarded become the property of the College. 4. Those competitors who enter dissections for which prizes are not awarded but which show sufficient merit may be refunded such amount of the cost of production as the examiners deem fit. 5. The cost and risks of transport must be borne by the student. The College will not be responsible for any damage the preparations may sustain, but those of unsuccessful competitors residing at a distance will be carefully repacked and handed to the carriers for delivery at such address as may be specified by the student.

A CONGRESS OF CHILD STUDY.—A congress will be held in Berlin from Oct. 1st–4th under the presidency of Professor W. Münch for the purpose of discussing child study and matters connected with the care of children. In the mornings of each of the four days addresses will be given to the whole congress by selected lecturers. The afternoons will be devoted to the meetings of sections, of which the first deals with anthropology and psychology, the second with psychology and pedagogy, and the third with social and philanthropic endeavour. Among the subjects for discussion the following may be mentioned: the scientific examination of the capacity of children; the association of ideas in normal and defective children; the care of children just released from school attendance; the importance of open-air instruction in mathematics and natural science; sleep among the public school population of Berlin; and the importance of manual training in the education of defective children. An exhibition of materials which have been collected to form the nucleus of a German museum of education and child study will also be held. The exhibits deal with physical instruction, the hygiene of normal and defective children, teaching materials, school buildings, and equipment. A series of drawings by young pupils will also be shown. The contribution of five marks constitutes membership and entitles the member to attend all lectures and to a report of the proceedings. The secretary of the congress is Professor Moritz Schäfer, Berlin, N.W., Klopstockstrasse 24, from whom detailed programmes can be obtained.

UNIVERSITY OF LIVERPOOL: DEGREE CEREMONY.—The ceremony of conferring honorary and other degrees in connexion with the University of Liverpool took place on July 10th at St. George's Hall. The Chancellor (the Earl of Derby, K.G.) presided and amongst others present were the Lord Bishop of Liverpool, the Right Hon. Charles Booth, Mr. E. K. Muspratt (Pro-Chancellor), Principal A. W. W. Dale (Vice-Chancellor), the professors and staff of the University, and several mayors of surrounding boroughs. Dr. Peace, the city organist, contributed selections on the organ during the assembly of visitors and students. The Chancellor, in his address, alluded to the continued prosperity of the University and said that it was his agreeable duty to confer the degree of LL D., *honoris causâ*, upon the Right Hon. Charles Booth, P.C., F.R.S., D.Sc., D.C.L. The recipient was one whose life had been spent for the benefit of mankind. Professor Gonner, in presenting Mr. Booth, alluded to the great work accomplished by him in dealing with social and economic questions in London, in the organisation of dock labour, in the Poor-law, and in old age pensions. The Chancellor then formally admitted Mr. Booth amid cheers. Mr. Booth made a suitable acknowledgment of the honour conferred upon him. William Savile Henderson and Frederick P. Wilson, graduates of the Victoria University of Manchester, were admitted to the degree of Doctor of Medicine in the University of Liverpool. David Moore Alexander, James Leonard Hawkes, Gerald Joseph Keane, Robert Edward Knowles, Richard Howard Mole, and Herbert Francis Wolfenden were admitted to the degree of Doctor of Medicine. Wilson Bell, Charles William Budden, and Charles Owen Jones, graduates of the Victoria University of Manchester, were admitted to the degrees of Bachelor of Medicine and Surgery in the University of Liverpool. Frederick Thomas Alexander Lovegrove was admitted to similar degrees (*in absentiâ*). Upon the subject of the Students' Union an appeal was made last year which brought in £8000. A site had been provided in Ashton-street by the council and plans were under consideration and the architect had been appointed. Although £8000 had been assured £5000 were still wanted. The importance of such institutions was now recognised by all the younger universities.

PRESENTATION TO A MEDICAL PRACTITIONER.—Mr. John Mortimer, M.B. Lond., M.R C.S.Eng., the honorary consulting physician to the Exeter Dental Hospital, has been presented with three pieces of silver plate by the dental staff and board of management of that institution on the occasion of his marriage.

NATIONAL SOCIETY FOR EMPLOYMENT OF EPILEPTICS: THE COLONY, CHALFONT ST. PETER.—The thirteenth annual meeting of the governors of this society was held on July 16th at the London offices, Denison House, Westminster. The chair was taken by Mr. E. Montefiore Micholls and the reports of the honorary medical staff and the executive committee for the year 1905 were received and adopted. From the latter report it appears that the extensions of the Chalfont colony and the consequent increase in the number of colonists have necessitated the purchase of 150 acres of additional land at a cost of £5500, the total area of the colony being now 360 acres. The executive committee states that the considerable recent extensions in the colony buildings have not kept pace with the increase in the number of applications, the result being that all candidates, and especially the female candidates, have to wait a long time for admission. In view of the importance in epilepsy of providing the patient with early treatment it is a source of considerable anxiety to the committee to now that unless additional accommodation is speedily proided the period of waiting for female candidates may extend ver several years. The report of the honorary medical taff states that the general health of the colonists throughut the year was very good and that there was an entire reedom from any epidemic or contagious disease, and in his report also attention is called to the need for greater ccommodation. The colony at present has accommodation or 198 patients, a figure which represents probably less than ·5 per cent. of the epileptic cases in the country that would e suitable for reception in a colony.

ST. MARY'S HOSPITAL.—The annual distribuion of prizes to the students of the medical school took place t St. Mary's Hospital, London, on July 16th in the presence f a large number of visitors. The Dean (Dr. H. A. Caley), n the course of his report, said that the examination esults for the year had been satisfactory: 25 students had btained diplomas of M.R.C.S. and L.R.C.P. and 18 the I.B. degree of the Universities of Oxford, Cambridge, ondon, or Durham. He also added that St. Mary's was epresented by 148 former students in the services—64 in he Royal Army Medical Corps, 48 in the Indian Medical ervice, and 36 in the medical service of the Royal Navy. urgeon-General Sir Alfred H. Keogh, K.C.B., Director-General of the Army Medical Service, presented the prizes nd congratulated the school on being so well represented in he public services, especially in that branch to which he had he honour to belong. Sir Alfred Keogh afterwards unveiled bronze mural tablet in memory of seven members f the hospital and medical school who fell in the outh African war. The memorial bears the following nscription:—

> To the memory of the members of St. Mary's Hospital who lost heir lives while serving in South Africa.—Arthur Baird Douglas, ieutenant-Colonel 3rd Battalion Sherwood Foresters (Derbyshire egiment); Robert H. E. G. Holt, Captain, R.A.M.C.; George William uy Jones, Lieutenant, R.A.M.C.; George Uniacke Jameson, Second ieutenant 1st Battalion the Border Regiment; Cecil Courtenay arsons, Civil Surgeon; Reginald Percy Fort, Civil Surgeon; Edith anley, Gardener, Sister Army Nursing Service.

he tablet is placed in the entrance hall of the Clarence ving of the hospital.

DONATIONS AND BEQUESTS.—Under the will of he late Mr. Charles H. Cowell of Ipswich the East Suffolk Hospital will receive £500.—The Walsall Cottage Hospital, he Birmingham General Hospital, and the West Bromwich District Hospital will each receive £1000 by the will of the ate Mr. Frederick Birch of Birmingham.—The late Mr. rank Bailey of Tilgate, Crawley, and Mark-lane, City, after bequeathing certain legacies to relatives and friends, has eft the residue of his estate to his wife for life, with remainder as she may appoint, and in default of such appointment he has bequeathed certain of his property, estimated to be worth £80,000, to King Edward's Hospital Fund for London.—The following bequests have been made under the will of the late Mr. Francis W. Webb of London: £10,000 to found a nursing institute in Crewe, £2000 to endow a bed at University College Hospital (preferably to employees of the London and North-Western Railway Company), £1000 to the Men's Convalescent Home at Rhyl, £1000 to the Devonshire and Buxton Bath Charity, £1000 to the Manchester Royal Eye Hospital, and £500 to the Royal Albert Asylum for Idiots and Imbeciles at Lancaster.

THE LONDON HOSPITAL.—Mr. R. B. Haldane, Secretary of State for War, distributed the prizes to the successful students at the London Hospital in the library of the Medical College of that institution on July 13th. Mr. Haldane afterwards addressed the students on the subject of medical science, and in the course of his remarks observed that a lesson should be taken from the science of medicine which taught that the healing of the body depended on the understanding of the principles upon which life was governed.

Parliamentary Intelligence.

HOUSE OF LORDS.

MONDAY, JULY 16TH.

County Council and Ambulance Service.

ON the third reading of the London County Council (General Powers) Bill Lord MONKSWELL endeavoured to have reinserted the proposals, which had been struck out by the Select Committee, to empower the Council to establish and maintain an ambulance service for dealing with cases of accident and illness in the streets. He could not make out why the committee had struck out the proposal.—Lord LEIGH pointed out that no city approaching London in size was without a proper ambulance service.—The chairman of the committee, the EARL of CAMPERDOWN, contended that it was impossible to pass a scheme of which no details were given.—It was then stated by Earl BEAUCHAMP that the Government could not advise the House to agree to Lord Monkswell's suggestion. In the opinion of the Home Office the scheme had not yet received that mature consideration which it ought to have before complete power was given to the County Council. The Secretary of State believed that it would be better to follow the line of developing the resources already existing in London than by a revolutionary change to inaugurate an entirely new system, and he had summoned a conference representing the London County Council, the Metropolitan Police, and the Home Office to consider what should be done. It was not unlikely that a committee would be appointed from these three bodies to formulate a scheme.—Lord MONKSWELL expressed his satisfaction with this announcement and the matter dropped.

HOUSE OF COMMONS.

THURSDAY, JULY 12TH.

A Vaccination Case.

Mr. MONTGOMERY asked the President of the Local Government Board whether he was aware that Mr. W. C. Palmer of Merridge, Spaxton, near Bridgwater, applied on Sept. 29th, 1904, to the Bridgwater county petty sessional magistrates for a certificate of exemption from vaccination of his child and was refused; that subsequently he was prosecuted for refusing to have his child vaccinated; that the same bench made an order, with 10*s.* 6*d.* costs, directing him to have the child vaccinated, and afterwards fined him 20*s.* and 2*s.* costs for disobeying that order; that goods to the value of £10 had been seized to be sold in liquidation of the fine and costs which Mr. Palmer refused to pay on the ground that they were illegally imposed; and whether, in the circumstances, the President of the Local Government Board would countermand such sale.—Mr. GLADSTONE replied: My right honourable friend has asked me to answer this question. I have no information with regard to the facts of the case beyond that furnished by the honourable member in the question, but assuming his statement to be accurate I may say at once that neither I nor any other department of the Executive Government have power to interfere with the execution of a warrant of distress issued by a court of competent jurisdiction. It does not appear on what ground the validity of the magistrates' order is disputed, but if any question of law is involved that could only be determined by a court of law.

Fees for Vaccination.

Mr. JOHN JOHNSON asked the President of the Local Government Board whether he had taken any steps in the direction of reducing the high fees paid for vaccination; if so, what steps; and, if nothing definite had been done, would he say when the grievance complained of by the local authorities was likely to be redressed.—Mr. JOHN BURNS answered: I have not at present definitely decided what shall be done in this matter. I am giving attention to it and I will come to a decision as early as may be practicable.

MONDAY, JULY 16TH.

Conscientious Objectors.

Mr. LEHMANN asked the Secretary of State for the Home Department whether he was aware that Spencer Bray, J. J. Vann, and S. Bruin, of Blaby, in Leicestershire, were on Monday last committed to Leicester gaol, the first two for seven days and the last for 14 days, on orders under Section 31 of the Vaccination Act, 1867; and whether His Majesty's Government proposed to take any steps to alter the law so as to make such imprisonments impossible in future.—Mr. JOHN BURNS replied: My right honourable friend has asked me to reply to this question. I have no information as to the particular cases referred to, but I may point out that a parent would not be liable to any penalty under the Vaccination Acts for the non-vaccination of his children if he had obtained a certificate of conscientious objection under Section 4 of the Act of 1898. I am aware that the procedure with regard to obtaining such a certificate is not altogether satisfactory and I am considering whether some alteration might not properly be made in the law with regard to the matter.

Insurance of Lives of Children.

Mr. LEWIS HASLAM asked the Secretary of State for the Home Department whether, having regard to the fact that under the present laws affecting the insurance of the lives of children the death of a child might by means of insurance be a source of profit to the person insuring, he would consider the advisability of introducing a Bill to provide that there should be a limit to the amount payable on the death of a child, so that the amount payable should not exceed such as might be reasonably required to pay for the funeral expenses of the child.—Mr. GLADSTONE answered: I do not know whether my honourable friend is aware that by Sections 62–67 of the Friendly Societies Act, 1896, the sum for which a child under five years of age can be insured in one or more societies is limited to £6 and that by the Collecting Societies Act, 1896, Section 13, this limitation is extended to all industrial assurance companies. Great difficulties have arisen in the way of the numerous proposals which have been made to amend the law by further reducing this limit. I would refer my honourable friend to my reply to the honourable Member for the Tower Hamlets on Feb. 22nd last, in which I explained that the criminal law relating to this matter is already very severe, a parent who insures a child and then is guilty of cruelty or culpable neglect being liable to penal servitude for five years under Section 1, Subsection (4), of the Prevention of Cruelty to Children Act, 1904.

Experiments on Living Animals.

Mr. MACKARNESS asked the Secretary of State for the Home Department whether he could state when the committee which he proposed to appoint to investigate the subject of experiments upon living animals would hold its first meeting and of whom the committee would consist.—Mr. GLADSTONE answered: A Royal Commission on this subject is about to be appointed and the names of the Commissioners will be announced in due course when His Majesty has approved of them.

Medical Inspection of School Children.

In the course of the debate on the Education (England and Wales) Bill Mr. TENNANT proposed to amend one of the clauses in order to secure the compulsory medical inspection of children attending the schools. Nearly all the speakers supported the honourable Member.—Mr. BALFOUR expressed himself strongly in favour of compulsion. But he would have the scheme carried out on a general scientific plan—a plan applicable to the whole country, a plan which would enable them to compare area with area, children under one condition with children under another condition, and the children of one generation with the children of the next. When they had done that, and not till then, they would have some really solid scientific basis for what was now too often merely rhetoric and speculative conclusions about the effect of modern civilisation upon the health and progress of the race.—Mr. BIRRELL confessed that in this matter he was in the hands of the House. He was willing to submit to the judgment of the House that it should be made obligatory on every local authority to provide for the medical inspection of every child on application for admission to a public school and on such other occasions as the Board of Education might direct. The Board of Education was equally willing to receive inspiration from the House in the direction of strengthening its medical staff at headquarters for the purpose, not of carrying out the inspection of the schools—for that, of course, must be done by local medical men to be appointed by the local education authority—but of seeing that the local authorities were discharging the duties which they have at present power to discharge and also to keep in touch with what was going on in continental towns. But what he was not prepared to accept was the further suggestion that the Board of Education should prepare, generally for town and country, schemes for the medical inspection of school children. In order to deal with the matter according to the opinions of the House he was willing to put down for the report stage an amendment to the following effect: "It shall be the duty of every local authority to provide for the medical inspection of every child on its application for admission to a public elementary school and on such other occasion as the Board of Education may direct or the local education authority may think fit."—Mr. TENNANT accepted this promise and the further discussion of the subject was postponed until the report stage.

TUESDAY, JULY 17TH.

Another Vaccination Case.

Mr. JOHN TAYLOR asked the President of the Local Government Board whether he was aware that, in the prosecution of Mr. Dixon at Chester-le-Street police court on July 4th, the public vaccinator stated that he was the private medical attendant of the defendant, that the child in question was not well enough in health to be vaccinated within the period provided by statute, that had he called at the home he could only have postponed the vaccination for two months, but that his scale of payment was not sufficient to recompense him for calling at the home unless he could perform the vaccination; whether it was the duty of the public vaccinator, in cases where, in his opinion, children were too delicate or too ill to render vaccination advisable, to furnish the parents with certificates of postponement; and whether he would take steps to see that such protection was afforded to parents in the Chester-le-Street union.—Mr. JOHN BURNS answered: It is the duty of a public vaccinator to postpone the vaccination of a child if, at the time of his visit, the child is not, in his opinion, in a fit and proper state to be successfully vaccinated. I understand from the public vaccinator referred to in the question that he always adopts this course and that he did not make the statement attributed to him as to the insufficiency of his scale of payment to recompense him for calling at the home unless he could perform the vaccination. He further states that in the particular instance mentioned his partner was Mr. Dixon's medical attendant and that the child had been delicate until the age of about four and a half months but was fit for vaccination at the time the father told him that he would have the child vaccinated by his own medical man.

BOOKS, ETC., RECEIVED.

CHURCHILL, J. AND A., 7, Great Marlborough-street, London, W.

Surgery, its Theory and Practice. By William Johnson Walsham, F.R.C.S. Eng., M.B. & C.M. Wisbech, North Cambridgeshire Hospital.—Resident Medical Officer.

Worcester General Infirmary.—House Physician. Salary £80 per annum, with board and residence.

The Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies as Certifying Surgeons under the *Factory and Workshop* Act at Blakeney, in the county of Gloucester, and at Blaydon-on-Tyne, in the county of Durham.

Births, Marriages, and Deaths.

BIRTHS.

Cory.—On July 10th, at Manor House, Soham, Cambs, the wife of *C. G. Cory, M.R.C.S., L.R.C.P., of a son.*

Cuff.—On the 16th inst., at The Lodge, Ashtead, Surrey, to Dr. and Mrs. Herbert Cuff—a daughter.

Harneis.—On July 12th, at Amhurst-road, Hackney, the wife of T. W. Morcom Harneis, M.R.C.S. Eng., L.R.C.P. Lond., of a daughter.

Inkson.—On July 16th, at Wrottesley-road, Woolwich, *the wife of* Captain E. T. Inkson, V.C., Royal Army Medical Corps, of a son.

McMurtry.—On July 12th, at East-hill, Wandsworth, S.W., the wife of W. D. McMurtry, L.R.C.S. & P. Edin., L.F.P.S. Glasg., of a daughter.

Walsh.—On July 10th, at Prospect-road, Old Brompton, Chatham, the wife of Fleet Surgeon J. J. Walsh, M.B., R.N., H.M.S. *Blenheim*, of a son.

MARRIAGES.

Fairweather—Bell.—On July 12th, at the Cathedral, Rochester, Francis Harold Fairweather, M.D., of Chatham, to Emily Maud, youngest daughter of J. Vincent Bell, M.D., of Rochester.

Maitland—Wilkin.—On July 12th, at Perivale Church, A. Derwent Maitland, M.R.C.S., L.R.C.P., L.S.A., to Effie, youngest daughter of Captain and Mrs. *Wilkin*.

Newbolt—Elliot.—July 11th, at St. Bride's Church, Liverpool, by the Rev. Bernard C. Jackson, M.A., George Palmerston Newbolt, M.B., F.R.C.S., of 42, Catharine-street, to Lila, only daughter of the late *John Elliot*, Esq., *Canonbie, Dumfriesshire*.

DEATHS.

Blackburn.—July 7th, at Ivy House, Barnsley, John Blackburn, M.R.C.S., aged 72. Interred at *Bradfield*, near Sheffield, Tuesday, July 10th.

Eddowes.—On July 11th, at Burleigh Fields, Loughborough, John Henry Eddowes, M.D., J.P., in his 8[illegible]th year.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

AN ANTIVIVISECTION FOUNTAIN.

LAST week a proposal to erect an "antivivisection" fountain in memory of a dead dog in the Latchmere Recreation Ground, Battersea, was discussed by the Battersea borough council. A year ago or thereabouts the council agreed to accept the fountain from the International Antivivisection Council. There was to be an inscription which some persons regarded as libellous. At the meeting it was recommended by the highways committee that the Antivivisection Council should be informed that the fountain may now be erected. A proposal was made to defer the matter *sine die*. This was violently opposed. Wild statements were made in respect to the "torture of animals" and "the dishonest use of money which working men had contributed to hospitals." A shorthand writer, understood to represent University College, was asked to retire and it was asserted that members of the council had given information to the College the authorities of which had written that proceedings would be taken if the fountain with the inscription were erected. On the other hand, the secretary to the Antivivisection Council wrote offering to deposit money for the defence. Borough councillors asserted that if medical students came to Battersea "to make a disturbance and smash the fountain" they would find other than passive resisters to deal with. Dr. L. S. McManus, who is a member of the council, characterised the denunciation of the medical profession as humbug. On a vote being taken 29 voted for the reception of the fountain and 19 against.

UNMANNERLY.

To the Editors of THE LANCET.

SIRS,—I was surprised to read in THE LANCET of July 14th the letter signed "L.R.C.S. & L.R.C.P. Edin." There was nothing in my letter that could possibly be construed into an attack on the Scottish Conjoint Diploma. As you explained in a footnote—though it should have been obvious enough—my introduction of details of qualifications was merely to show that Mr. D would have suffered no loss of dignity by meeting me. In a precisely similar case last year, where I again acted for Mr. A, I had a very agreeable and instructive consultation with the medical practitioner in charge of the case.

I am sorry your correspondent has taken umbrage at what I wrote, but I feel sure that if he will read my letter again he will see that the injury is imaginary. I am, Sirs, yours faithfully,

M.D. Lond.

July 14th, 1906.

To the Editors of THE LANCET.

SIRS,—I beg to offer my opinion in the above case, taking the facts to be as stated. My sympathies are with the medical attendant of the sick man. If the patient and his relatives were satisfied with the medical attendance it would have been well for the employer not to have interfered. If the employer wished to do acts of kindness he could have sent sick-room delicacies, &c., approved by the patient's medical man. When the medical man attending offered to meet a consultant I consider he did all that was necessary. The fact that Dr. C—the complainant—was the employer's medical man fails, to my mind, simply on that account to place him on a higher plane than the foreman's medical man. If the employer thought fit to say "impolite things" of his workman's medical man I think they were undeserved and uncalled for. Surely Dr. C does not seriously ask one to believe that because a general practitioner happens to be on the staff of a hospital he is, *ipso facto*, superior to general practitioners who are not? With such a weak case I consider Dr. C's appearance in public print unfortunate. I am proud to sign myself

July 14th, 1906. ANOTHER L.R.C.P., L.R.C.S. EDIN.

*** "M.D. Lond." states definitely above what we knew (otherwise his letter would not have been printed)—viz., that he assumed no superiority. He quoted his position as showing that no obvious inferiority could justify the brusque treatment that he received.—ED. L.

THE TEETH OF WORKING-CLASS CHILDREN.

A MOVEMENT having for its object the better care of the teeth of working-class children is making considerable progress in certain contiguous districts in the centre of Europe. One of the leaders is Dr. Jessen of Strasburg who has succeeded in establishing a school dental clinic at that town. To it the school children are sent regularly for examination. Each child is quickly examined, the result is noted on a card, and a note is added as to the treatment required. The dental clinic does not press children to submit to treatment but it is ready to undertake the work if need be. This it does at a cost of about £320 per annum, almost 3½d. per head of the school population. The expenses are met by grants in aid and voluntary contributions. With treatment teaching goes hand in hand; the child is instructed in the use of a tooth-brush and the teacher discusses teeth, their uses and their care, in his natural history lesson soon after his class returns from the examination. Wall pictures illustrating the growth of the teeth are now to be had for demonstration purposes. In Wiesbaden and Mülhausen school dental clinics will be opened shortly. The initial expense at Mülhausen (90,000 inhabitants) is calculated at £650. In Winterthur Dr. Helbing has lately completed an examination of the teeth of 2400 children. He finds that only 1 child in 40 has a perfect denture and that over 23 per cent. of the teeth examined are bad. As a result of his representations the local school board has decided to add the examination of pupils' teeth to the duties of the medical officer who undertakes the medical examination of the newly enrolled children. At Langenthal, a railway centre and an agricultural district of the canton of Berne, the school board issues circulars to parents enjoining them to pay attention to the state of their children's teeth. For some time past the board has bought tooth-brushes wholesale and has retailed them at slightly over cost price to the children. In this manner it makes a slight profit which is expended in distributing tooth-brushes gratis among poor children.

ADVERTISEMENTS IN PUBLIC URINALS.

To the Editors of THE LANCET.

SIRS,—Could not some method be devised for putting a stop to the placarding of public urinals with all sorts of filthy quack advertisements? Surely the various authorities might put up notices threatening to punish any person who shall affix an advertisement of any kind on the walls of public urinals, either inside or out, and the person who is commissioned to look after these places might be ordered to take round with him each morning a pail and brush and scrape down any advertisements so appearing. I am, Sirs, yours faithfully,

F. R. A.

July 13th, 1906.

*** Some authorities are more active than others in doing exactly what our correspondent suggests.—ED. L.

CURIOUS NAMES.

IN the column of the *Standard* of July 18th headed Births, Deaths, and Marriages the surname "Godbehere" appears in the deaths. Such names as Deogratias, Deusdedit, and the like were common among the North African Christians of the fourth and fifth centuries. Every one will remember Adeodatus the son of St. Augustine. In these cases the names were probably translations of Semitic names, such as Mattathiah or Nathaniel, but in English such names are very rare and it would be interesting to trace the steps by which they came to be adopted into our language. The members of the medical profession come more into contact with all sorts and conditions of men than do those of any other profession, the clergy possibly excepted. Some years ago we remember a medical man practising in Norfolk made an interesting collection of curious and out-of-the-way Christian names existing in remote districts of that county and we hope that any of our readers who come across similar names, either Christian or surname, will communicate them to us. Names are always of interest, for in them is often preserved much historical fact dealing with racial characteristics and the like.

THE ARGENTINE BOOT HEEL.

WE have received from the Patent Argentine Heel Company specimens of their boot heels. The heel consists of two layers of leather with one layer of vulcanised indiarubber between them. The surface which touches the ground being leather there is not the same danger of slipping in wet weather as occurs with an indiarubber heel in which the rubber is in contact with the pavement. One of our representatives who has tried these heels fitted to an ordinary pair of shoes for walking about London reports that he finds them more comfortable than plain leather heels. They can be obtained from all bootmakers.

THE PREPARATION OF INFANTS' FOOD.

AT the invitation of Mr. Cornelius Hanbury, the chairman of Messrs. Allen and Hanburys, Limited, a number of medical men, scientific experts, and press representatives visited the works of the firm on Tuesday last at Ware in Hertfordshire, in which the manufacture of the "Allenburys foods" and the "Allenburys diet" is carried on. A special train was provided for the visitors at Liverpool-street and there were present at the inspection about 200 ladies and gentlemen. The various processes by which the Allenburys foods are prepared were watched with interest. An advantage of the works being situated at Ware is that this town is in the middle of rich pasture-land, so that the milk used in the foods is perfectly fresh and not exposed to the contaminating influences of a long journey. As to the composition of these foods we have already given our analyses of them under the heading of Analytical Records in THE LANCET of March 24th, 1894, p. 748. The manufacturers always lay stress on the necessity of the directions as to how to use the food being carefully followed. Thus one important direction as meeting the objection that these foods are sterilised and therefore lacking in the fresh or vital element of raw milk is to supplement the food with the occasional use of raw meat juice or fresh grape juice, or white of egg. The foods are malted, contain a good proportion of cream, and the milk proteid is digestible, the casein clotting only loosely or not at all, whereas in the case of cow's milk the casein clots densely and in that form is indigestible. At a luncheon which followed the inspection Mr. Cornelius Hanbury gave a history of the manufacture of the Allenburys foods and drew attention to the fact that they always received the best advice that could be given on the subject of infant feeding, and as views advanced so they introduced any modifications that might be held to be necessary in the preparation of the foods.

◆

A. Z. is thanked for a communication which we will publish in an early issue.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

THE Index to Vol. I. of 1906, which was completed with the issue of June 30th, and the Title-page to the Volume, were given in THE LANCET of July 7th.

VOLUMES AND CASES.

VOLUMES for the first half of the year 1906 are now ready. Bound in cloth, gilt lettered, price 18*s.*, carriage extra.

Cases for binding the half-year's numbers are also ready. Cloth, gilt lettered, price 2*s.*, by post 2*s.* 3*d.*

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD.	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

During the week marked copies of the following newspapers have been received: *Morning Leader, Globe, Bristol Times, Cork Constitution, Dundee Courier, Morning Post, Bolton Chronicle, Bristol Mercury, Westminster Gazette, Birmingham Post, Daily Telegraph, Hampshire Advertiser, Southampton Echo, Daily News, Wolverhampton Midland Express, Newcastle Chronicle, Herts Mercury, Scientific American, Glasgow Herald, &c.*

Communications, Letters, &c., have been received from—

A.—Dr. F. W. Andrewes, Lond.; Dr F. W. Alexander, Lond.; Messrs. R. Anderson and Co., Lond.; A. R. D.

B.—Mr. H. Barling, Birmingham; Sir Lauder Brunton, Lond.; Dr. T. P. Baldwin, Lond.; Mr. P. T. B. Beale, Lond.; Bureau of Science Manila, Librarian of; Monsieur C. Berthier, Paris; Mr R. H. Bremridge, Lond.; Mr W. Bernard, Buxton; Messrs Bates, Hendy, and Co., Reading; Board of Agriculture and Fisheries Lond., Secretary of; *British Gynæcological Journal.*

C.—Dr. Harry Campbell, Lond.; Children's Country Holiday Fund, Secretary of; Messrs Chivers and Sons, Histon Cambridge; Dr J. Burton Cleland, Perth, Western Australia, Dr. A. G. R. A Lecture

ON

HEAD-NODDING WITH NYSTAGMUS IN INFANCY.

Delivered at the Hospital for Sick Children, Great Ormond-street, London, W.C.,

BY GEORGE F. STILL, M.A., M.D. CANTAB., F.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE HOSPITAL; PHYSICIAN FOR DISEASES OF CHILDREN AT KING'S COLLEGE HOSPITAL; PROFESSOR OF DISEASES OF CHILDREN, KING'S COLLEGE, LONDON.

GENTLEMEN,—Under various names, such as "spasmus nutans," "head-nodding of infants," and "head-shaking with nystagmus," there has been described a curious and somewhat uncommon disorder which is worthy of attention, if only on account of the unnecessary anxiety which it arouses in the minds of those unfamiliar with its occurrence. The earliest published record of which I am aware is one by Ebert in 1850, but it was not until the late Dr. W. B. Hadden of this hospital published his series of observations in 1890 that the disorder became generally recognised. 31 cases of this affection have come under my own observation; 19 of the patients were boys and 11 were girls (the sex was not noted in one case); this disproportion, however, may be accidental, for in a series recorded by Dr. J. Thomson[1] there were 15 boys and 20 girls. The disorder is almost limited to infancy—i.e., the first two years of life, although, as I shall point out, in rare cases it lasts beyond this limit. In 22 out of 28 cases in which the age at onset could be determined the disorder began between the ages of five months and 12 months; of four which began earlier only one was said to have begun as early as the age of three months, and two began after the first year, both before the age of 14 months.

Sketched in outline the clinical picture is somewhat as follows. As the child sits on his mother's lap there is, perhaps, nothing abnormal to be seen for a minute or two, then as the child fixes his gaze on some object the head begins to nod at the rate of about eight or ten nods within five seconds, after which there is a pause of varying length, and so with irregular intervals short series of noddings occur more or less frequently so long as the child is in the sitting position. Hardly less striking than this rhythmic unsteadiness of the head is the curious way the child has of looking at objects out of the corner of his eyes with the head slightly averted and the face turned slightly downwards, reminding one of the behaviour of the Beaver in "The Hunting of the Snark," for, as you may remember,—

> "Whenever the butcher was by,
> The Beaver kept looking the opposite way
> And appeared unaccountably shy."

The other feature which attracts attention is the exceedingly fine rapid nystagmus which is peculiar in being so much more marked in one eye than in the other, that it may appear to be actually limited to one eye, a point which the mother herself has usually noticed. These three symptoms, the head-nodding, the tendency to look out of the corner of the eyes, and the nystagmus, constitute the characteristic features of spasmus nutans which I shall now consider in more detail.

SYMPTOMS.

The rhythmic movement of the head is not necessarily an antero-posterior affirmative nod as the term "head-nodding" might seem to imply; indeed, so far as my own observations go, a lateral shake of the head as in negation would appear to be a commoner movement. Sometimes also the movements vary, being at one time antero-posterior, at another negation, whilst more rarely there is a simultaneous combination of the lateral and antero-posterior movements producing a sort of pendulum movement. In 22 cases I have noted the variety of movement: 11 patients showed only lateral rotation (negation); six showed only antero-posterior nodding; four either of these movements at different times; and one the combined pendulum movement. The rate of movement varies from 60 to 120 nods per minute, the series of nods lasts sometimes only for four or five seconds, and sometimes as long as 30 seconds. I have noted in one case three bouts of nodding in six minutes but they may be more frequent or may occur much less often; there is no regularity in the intervals, they depend largely on the child's occupation. I have thought that the nodding occurs chiefly when the child fixes his gaze upon an object in a sort of abstraction but that the movements cease directly the child is aroused to active attention. In some cases I have specially noted that the movements could be stopped by attracting the child's attention. Perhaps there is some variation in this respect, for one mother informed me that the movements were specially noticeable when the child was watching children playing in the street, and another said that her child showed the nodding chiefly when not interested by anything in particular. The head movement occurs only when the child is sitting with the head unsupported; it ceases, therefore, when the child is lying in a cot or leaning the head against the mother's arm. This is a point upon which I would lay some emphasis, for it is of some importance in diagnosis; the condition might easily be overlooked if the child is seen only lying in a cot. Moreover, there is another movement, head-rolling, which must be distinguished from the head movement of spasmus nutans and which occurs chiefly when the child is lying down. The range and vigour of the movements vary considerably in different cases and in the same case at different times; in some they are so slight as to be easily overlooked while in others they are obvious to all. Twice I have seen the antero-posterior nodding so forcible as almost to shake the child's bonnet off, but this is, I believe, quite exceptional. But whether the movements be slight or vigorous they are obviously involuntary and in this way differ from the much commoner "head-rolling" which has the appearance of a voluntary movement.

I have already alluded to the occurrence of head-nodding when the infant is sitting gazing at some object in an absent-minded sort of way. And this leads me to remark on the curious tendency of these children with spasmus nutans to fall into an absent-minded stare, a sort of "brown study" which seems hardly natural for an infant. But there is nothing whatever in these moments of abstraction to suggest *petit mal*. The child takes notice directly attention is drawn to sight or sound; there is no change of colour, no tendency to any epileptiform manifestation—in fact, no ground whatever for regarding this peculiarity as due to *petit mal*. I wish to lay great stress upon this point, for it has been stated that children with spasmus nutans show a special liability to *petit mal*. So far as my own observations go I have not seen the least tendency to epilepsy of any sort. Very remarkable is the habit these infants have of looking out of the corner of the eyes while the face is turned in the opposite direction and slightly downwards. So characteristic is this when present—and I think it is present in many cases—that it should at once suggest spasmus nutans. The parents themselves have often noticed it. In one of my cases it was the first complaint that the infant had recently begun to look out of the corners of his eyes "in a funny, coy way," which had made the father, a medical man, fear some serious cerebral disease. I have no explanation to offer for this curious symptom. I have heard it suggested that it is due to an effort to obtain fixation of the eyes which nystagmus renders difficult, but this can hardly be so, for I have seen this sideway gaze very marked in two of the exceptional cases where there was no nystagmus. "Gaze" I say rather than "glance," for during this action perhaps even more than at other times the infant is apt to stare fixedly as if in one of those "brown studies" to which I have referred. This phenomenon may be noticeable several times within five or ten minutes.

The nystagmus which with the head movement constitutes the chief feature of spasmus nutans is characteristic and peculiar in certain respects, and chiefly in two points. 1. Its unilateral predominance. It is almost invariably much more marked in one eye than in the other—indeed, in some cases it appears to be actually unilateral. This unilateral predominance, apart from any unilateral lesion of the media or fundus, is, so far as I am aware, excessively rare apart from this particular disorder. 2. Its onset without apparent cause in an infant a few months old, and its complete disappearance after a few weeks or months. Such temporary nystagmus in infancy without ocular lesion or any evidence of gross cerebral disease is, I believe, almost peculiar to spasmus nutans. The nystagmus differs also from that due to some other conditions in being exceedingly fine and rapid. It may be vertical, horizontal, or rotary, and Dr. Thomson has observed it to be convergent instead of conjugate in some cases. I have seen it to be associated with vertical nystagmus of the upper eyelid but this is unusual. I have not observed the rhythmic contraction of the pupil (hippus) which some writers have recorded; Dr. Thomson noted this in four out of 35 cases.

---

[1] International Contributions to Medical Literature, Festschrift, May, 1900.

The onset of nystagmus in spasmus nutans may precede the head-shaking by several weeks or even months. In one of my cases it was stated to have been present three months before the head-nodding began; more often the head movement is the first symptom that attracts attention and the nystagmus may appear later. From this variation in the order of occurrence of these symptoms it might be conjectured that cases would occur in which one or other symptom was lacking altogether and there can be little doubt that not only does the characteristic head-nodding occur *sometimes without nystagmus at any period of the disorder*, but the nystagmus may be the only manifestation of spasmus nutans, if the affection may be so called when head-shaking is entirely absent. The evidence of this lies in the occurrence in infants of nystagmus which has the characteristic features mentioned above and which shows the same age incidence, seasonal variation, and relation to rickets, and the same temporary character, a duration of weeks or months, as does the nystagmus which is associated with head-nodding. I have included in my series of 31 cases three in which was shown this nystagmus alone and two in which was shown the characteristic nystagmus associated not with head-nodding but with the much commoner quasi-voluntary movement head-rolling, an association which is perhaps to be regarded as accidental. Of the 26 cases with head-nodding 23 patients showed nystagmus sooner or later (in two of these it was extremely slight and perhaps open to doubt); only two showed no nystagmus at any time.

With this description of the symptoms of spasmus nutans I would mention the case of an infant, aged five months, in whom not only were the antero-posterior noddings of the head unusually marked but there was also some shaking of one arm. These symptoms had lasted for some days when I saw the child and I heard from Dr. C. W. Cooke of Willesden, under whose care the child was, that they passed off soon afterwards without leaving any ill effect. In one other case I have noted some shakiness of the arms and Dr. Thomson mentions this symptom as present in two cases in his series.

ETIOLOGY.

I turn now to the consideration of the etiology of spasmus nutans. Rickets is present in a large proportion of the cases. In 20 out of 25 cases in which I have noted this point the patients showed some degree of rickets but only four showed severe osseous rickets; in most it was particularly noted that the evidence of rickets was definite but slight. The occasional absence of rickets shows that rickets is not an essential factor; moreover, in the rare cases in which the disorder begins at as early an age as two or three months rickets is not likely to have been a causal factor even if it is found later. It is, I think, clear that spasmus nutans does not stand in so close a relation to rickets as do such conditions as laryngismus stridulus, facial irritability, and tetany phenomena which in infancy are almost always associated with well-marked and often severe degrees of rickets. It is, indeed, noteworthy how seldom spasmus nutans keeps company with any of these phenomena, which are so closely associated together that the presence of any one of them raises an expectation of the others and which, like convulsions, are well recognised as expressions of the nervous instability of rickets. In my own series one patient showed facial irritability; in Dr. Thomson's series of 35 cases two showed laryngismus stridulus with or without facial irritability and two others showed facial irritability without laryngismus. As a predisposing cause, however, rickets must be regarded as a frequent factor in the etiology of spasmus nutans.

The relation of this disorder to dentition is specially noteworthy. The onset of spasmus nutans is most commonly between five and 12 months of age, the period when the worry of dentition begins; the affection rarely persists after the end of the second year, the end of the first dentition. Moreover, it was evident in some of my cases that just before the eruption of a tooth the head movements and also the nystagmus were increased, while they at once became less when the tooth was through the gum. My own opinion is entirely in agreement with that of Henoch who regarded the irritation of teeth as the usual exciting cause of spasmus nutans. I think, however, that it is quite likely that other forms of peripheral irritation may also act as exciting causes, and some support is given to this view by the closely comparable phenomenon to which Mr. W. T. Lister has drawn my attention, the occasional production of temporary nystagmus by ear-syringing. Preceding illness or injury would seem to have determined the onset in some of my cases; in one with nystagmus only the nystagmus began three days after an attack of diarrhœa and vomiting; in another it began during convalescence from diphtheria; in two others during convalescence from infantile scurvy; in one case head-nodding began four days after an attack of diarrhœa, in two just after bronchitis, and in one a few hours after a fall on the head Its occurrence in rickety children and after the exhaustion of various illnesses or the shock of an injury, and its very close relation to dentition and the exacerbations just when a tooth is in process of eruption, all suggest that spasmus nutans is a functional disorder depending upon an acquired or congenital nervous instability with some peripheral irritation as an exciting cause.

The defective-light theory.—Of recent years there has been put forward a theory which is worthy of careful consideration—namely, that spasmus nutans is due to living in ill-lighted dwellings; dimness of light, it is supposed, causes deficient fixation of vision, and, moreover, the infant throws his eyes into an unnatural and strained position in attempting to look towards the window. To this strain upon the ocular muscles is due the nystagmus; the head movements are secondary to the nystagmus. This is the view put forward by Raudnitz.[2] The arguments adduced in its favour are: (1) the fact that infants with spasmus nutans often live in dark dwellings; (2) the rarity or non-existence of the disorder amongst the wealthier and consequently better housed; (3) the onset of the disease nearly always during the dark months of the year; and (4) the analogy with miners' nystagmus, with which there are known to be associated in rare instances some rhythmical swaying movements of trunk and head.

Now I venture to think that in spite of the above apparently strong arguments there are grave difficulties in accepting the defective-light theory.

1. It is quite certain that spasmus nutans may occur in infants living in well-lighted dwellings. I have inquired specially into this point in 27 cases; in four of these I was able to visit the home, in the rest my inquiry was only by careful interrogation not by actual visiting and is therefore less convincing than actual visitation would be. In four cases only did the home appear to be ill lighted and in some of these the child was hardly taken out of doors at all. In 23 out of the 27 cases, including the four which I visited myself, there appeared to be no reason for regarding the room in which the child chiefly lived as ill lighted, and in several cases it was specially noted that the rooms were light and sunny. But in considering the question of light it is obviously necessary to take into account to what extent the child lives indoors. Some of my patients were taken out daily and in one case it was particularly stated that the child was taken out much every day and "in all weathers."

2. The disorder is undoubtedly seen chiefly in hospital practice, but I have seen it in three cases in private practice amongst people in comfortable circumstances and well housed, once in the infant of a medical man whose nursery was an excellently lighted room. It must be remembered also that rickets, which most observers have regarded as a predisposing cause, is commoner amongst the hospital class than amongst the well-to-do.

3. The seasonal incidence of the disease is, indeed, remarkable. In 21 of my cases the onset could be dated with some degree of accuracy: January, 7; February, 5; March, 1; April, 0; May, 0; June, 0; July, 1; August, 0; September, 2: October, 1; November, 1; and December, 3. In six others the date could be determined with less certainty, thus: January, 1; February, 1; March, 3; and November, 1. So that out of 27 cases 17 began within the three months December to February. Only one began during the five months April to August. These figures agree with those collected by Dr. Thomson and addition of his statistics to mine shows that 86 per cent of the cases of spasmus nutans have their onset during the five months November to March. But the special incidence of the disorder in these comparatively dark winter months is not necessarily connected with deficiency of light and I would point out that

---

[2] Jahrbuch für Kinderheilkunde, Band xlv., p. 145.

ryngismus stridulus, another nervous disorder associated ith rickets and one which can hardly be attributed to eficiency of light, has a very similar seasonal incidence; its nset is, it is true, rather more often in March than in anuary, but according to my own statistics no less than 0 per cent. of the cases have their onset during the five onths November to March. It would seem, therefore, that uring this season there is some influence apart from eficiency of light favouring the onset of certain nervous isorders in connexion with rickets.

4. The analogy with miners' nystagmus can hardly be said o support very strongly the defective-light theory, for it is he opinion of experts now that such nystagmus is due uch less to the bad light than to the strained position of he eyes in this occupation; and nystagmus is known to ccur from a similar cause in other occupations in which a trained position of the eyes is usual, although the work is one in broad daylight. Moreover, the miners' nystagmus oes not show, so far as I have been able to ascertain, the nilateral predominance which is so striking a feature in the ystagmus of spasmus nutans.

Lastly, this theory seems to assume that the head movements are secondary to the nystagmus; whereas clinical xperience shows that the head movement often precede he nystagmus and occasionally no nystagmus appears at ny time.

Prognosis.

Spasmus nutans usually passes off after a few months, eaving no ill-effects; occasionally it lasts only from two to hree weeks, more often it lasts from three to 12 months; it arely lasts beyond the end of the second year. I have, howver, seen nystagmus still present in one case at the age of our years.

As already stated, I know of no special relation between pasmus nutans and epilepsy, minor or major; indeed, I ave not seen a single case in which the child has developed pilepsy either during the persistence of, or subsequently to, pasmus nutans. I suspect that the tradition of such an ssociation has arisen from the description given by Ebert f cases of epilepsy with clonic jerking of the head under he same heading "Spasmus seu Eclampsia Nutans," an nfortunate confusion of disorders which differ widely both n their symptoms and in their course. In one of my cases a ingle convulsion occurred in the ten months during which pasmus nutans lasted, but it appeared to be an ordinary nfantile convulsion such as any rickety infant may have, and no others occurred during the subsequent period of observation (five months).

I have been asked several times whether the disorder will leave any injurious effect upon the intellect and I have kept notes in several cases of the child's progress in walking, in talking, and in intelligence. I have not found them more backward than other children, unless the degree of rickets happened to delay development, which it rarely did; but spasmus nutans, being an index of nervous instability, is, I think, likely to occur in children who will show nervous peculiarities at a later age. (I am not alluding to imbecility, though there would seem to be some special liability to this disorder in Mongol imbeciles; two cases in my series were "Mongols," and Dr. Thomson includes two cases in his series of 35 cases and alludes to another.) In several cases I have thought that the child long after all trace of the disorder had disappeared was a highly nervous or eccentric child without showing any lack of intelligence. One patient was sent to me subsequently for "spitefulness and screaming," another at the age of four years because it was "so nervous and screamed at the slightest thing." Apart, however, from this possible foreshadowing of later tendencies to neurosis, it is probably safe to give an unqualified good prognosis.

Diagnosis.

Spasmus nutans must be distinguished from a very rare congenital condition of nystagmus with head-nodding. This disorder, unlike spasmus nutans, is permanent, not transitory. In a case under my care, a boy, aged seven years, apparently of average intelligence, showed head-nodding very like that of spasmus nutans, but the nystagmus, which dated from birth, was coarser and less rapid than that usually seen in spasmus nutans and showed no unilateral predominance. The eyes, as in spasmus nutans, showed nothing abnormal apart from nystagmus.

Another curious movement to be distinguished from spasmus nutans is the head-rolling which is seen in infancy and sometimes in children just past infancy. It occurs chiefly when the infant is lying down—the child rolls his head monotonously from side to side on the pillow. The movement appears to be voluntary, whereas that in spasmus nutans appears to be quite involuntary; it is not associated with nystagmus.

Epilepsy with clonic jerkings of the head forward upon the sternum has unfortunately been called "eclampsia nutans" and by some writers "spasmus nutans," but apart from the name there should be little risk of confusion. The attacks consist of a series of forcible noddings of the head or bowing movements of the whole trunk, usually with loss of consciousness and other usual accompaniments of epilepsy. Nystagmus, if present, is only likely to occur as part of each attack, whereas in spasmus nutans it is to be seen just as often when the head is at rest as when the nodding is present; the epileptic nodding in infancy is associated almost always with idiocy sooner or later.

Treatment.

The very variable duration of this disorder and its frequent fluctuations in degree make it difficult to estimate the value of treatment. Diminution both of the head-nodding and of the nystagmus sometimes follows the use of sedative drugs and I have thought that phenazone was more valuable than bromide in these cases. At six months old half a grain, and at one year old one grain, of phenazone may be given. In some cases I have given a combination of bromide with cod-liver oil apparently with good results. The part played by rickets in predisposing to spasmus nutans suggests also the advisability of inquiring into the feeding and correcting any fault which may favour the rachitic tendency. I have no doubt also that cold or tepid douches as the infant sits in a warm bath tend to reduce the nervous instability and that confinement in a close, ill-ventilated room, whether well or ill lighted, increases this instability and is therefore to be forbidden. For this reason I have urged the parents to keep these children out of doors as much as possible, and I suspect that in the greater liability to confinement in a stuffy room with closed windows during the cold months lies the explanation of the seasonal incidence of spasmus nutrans rather than in any deficiency of light.

An Address

ON

PERICARDITIS IN CHILDHOOD.

Delivered before the Æsculapian Society on April 30th, 1906, to open a discussion on the subject,

By ALEXANDER MORISON, M.D. Edin.,
F.R.C.P. Lond. & Edin.,

PHYSICIAN TO THE GREAT NORTHERN CENTRAL HOSPITAL AND TO THE CHILDREN'S HOSPITAL, PADDINGTON GREEN.

Gentlemen,—An opening address written to provoke discussion upon a particular subject should touch upon many points without exhausting them and may express views which do not gain universal assent. In the following remarks the first of these conditions will certainly be found to be fulfilled, and should some of the conclusions arrived at not meet with entire approval I hope it may also be considered that they deserve discussion before modification, acceptance, or dismissal. It is on the whole a fortunate tendency of the normal human mind that it directs attention chiefly to the most dominant factors in any situation. This attitude has, however, the disadvantage that it withdraws attention from the investigation of possibilities which may often be of minor importance but which may also occasionally prove of primary consequence and yet escape detection. Surgeons and also physicians, who have sometimes missed the key to a situation by neglecting, for example, the examination of the rectum, have frequently emphasised the importance of such an investigation in obscure cases, even if the symptoms do not positively point to that structure as their source. I feel inclined on the same grounds to insist that, as a matter of routine, the condition of the pericardial sac should be particularly examined, because there are few physical conditions in disease which are so often left undetected as is pericarditis when the effusion or other morbid condition is not of a very obtrusive nature. I need not, perhaps, recall the oft-told tale which relates how a certain distinguished physician called in consultation detected a pericarditis which the very able family adviser had, much to his own annoyance, overlooked. The discoverer of the condition consoled his brother practitioner by remarking that it was perhaps as well that he had not detected it, as he might have been tempted to treat it! I have no doubt that the now deceased worthy to whom I refer had frequently himself missed a pericarditis and only found it post mortem, while his scepticism as to treatment embraced many conditions besides pericarditis, although in this instance it was probably in a measure wise.

In the early stages of the development of the heart in embryo that section of the cœlom which is ultimately shut off as the pericardial sac is, compared with the heart itself, relatively large, just as the whole embryo is, relatively to its amniotic sac, small. The heart grows to fill the pericardium until their relations are fixed by the attainment of the ultimate relative size of these structures. *Then* the heart fills the sac in normal circumstances so completely that only a very small quantity of fluid, a drachm at most in the adult and much less in the child, remains within it, to lubricate in health the movements of the ever-active organ. The *position* and dimensions of the heart thus become for clinical purposes those of the pericardium. But the distensibility of the sac is considerable and when it contains an excess of fluid its area is, relatively to the heart, much increased, as in early embryonic life, and to a certain extent this must be regarded as conservative. On the subsidence of such fluid contents, when this takes place and when at the same time the heart is affected by hypertrophy from some concurrent valvular lesion, as is often the case, the increase in size of the heart relatively to its containing sac also again reproduces the later relations of embryonic growth to which I have already referred. This increasing apposition of inflamed visceral and parietal pericardium is probably one of the causes which favour that adhesion of these surfaces, which is followed by still greater hypertrophy of the organ, more especially if at the same time adhesions have been established by inflammatory processes to structures outside the pericardial sac, such as the sternum, ribs, and pulmonary pleuræ.

It has frequently been remarked that statistics are of little value for determining the ratio in which related physical events occur in pathology and in medicine generally. While this is perhaps true if our object be to attain a fractional precision, it does not necessarily hold good when we desire by even a moderate number of cases to ascertain the drift of certain underlying general principles. My taking this view must form my excuse for examining a certain number of fatal cases of pericarditis in children which have occurred in the practice of my colleagues, past and present, and myself at the Children's Hospital at Paddington Green, and anatomical particulars of which have been preserved in the post-mortem records of that institution.

In 44 cases of acute and chronic pericarditis the cardiac valves were unaffected by disease in 12 instances. The pericardium was not adherent in six and is stated to have been merely inflamed in five. It was adherent in 17 cases either to the epicardium or to both this and extraneous structures, while in three instances there were costo-pericardial adhesions without adhesions between the visceral and parietal layers of the sac. In one case the adhesions were pleuro-pericardial. In the 12 instances in which the endocardium was unaffected the pericarditis was due to tubercle, pneumonia, or empyema. In the vast majority of the remainder, in which there was valvular lesion, the cause of the disease was acute rheumatism, the few exceptions being constituted by congenital disease or malformation of the heart. That is to say, the cases in which valves escaped simultaneous implication in the pericarditic process were due to localised conditions, spreading chiefly by contiguity towards the heart, from immediately neighbouring structures. The cases, on the other hand, which showed endocardial as well as exocardial disease were the result of a general blood infection, the agents of disease being carried by that all-permeating fluid to all the component parts of the organ. Indeed, the late Dr. Octavius Sturges, who drew attention to this feature of heart inflammation in children, abandoned very largely the use of terms denoting the separate inflammation of the endocardium, myocardium, and pericardium, and used, as a rule, the general term "carditis," because of the universal nature of the cardiac inflammation in many such cases.[1] Pericarditis, in a limited number of cases, may be the chief lesion even when the inflammation is of rheumatic origin and the removal of a pericardial effusion may in such cases be the chief object of treatment, as it may also be the chief cause of danger to life. But in the majority of cases the pernicious influence of pericarditis alone is gradually asserted and is frequently marked by a notable exaggeration of the conditions which produce hypertrophy of the heart and disorder of its action. This may be gathered from the weight of the organ noted in cases of valvular disease and in which it is additionally hampered by the presence of extraneous adhesions. Thus, in nine cases in which the valves were affected and the pericardium at the same time was adherent the following particulars as to age, sex, nature of disease, and heart weight attained may be gathered from the records I have mentioned:—

No.	Sex.	Age (years).	Nature of disease.		Heart weight.
1	M.	10	Aortic regurgitation.	Adherent pericardium.	16 ounces.
2	M.	5	Aortic and mitral valvulitis.	,,	Large.
3	F.	5	,,	,,	Rather large.
4	M.	7	Mitral valvulitis, aortic reflux.	Adherent pleuro-pericardium.	Much enlarged.
5	F.	11	Mitral and aortic valvulitis.	Adherent costo-pericardium (not visceral).	15½ ounces.
6	F.	11	Mitral reflux.	Much viscero-pericardial and costo-pericardial adhesion.	25 ounces.
7	F.	5½	,,	Pericardium adherent generally.	Very large.
8	F.	13	,,	Pericardium firmly adherent.	26 ounces.
9	M.	8	,,	Cor villosum; pericardio-sternal adhesion.	18½ ounces.
10	F.	11	,,	Pericardium not inflamed; two ounces of fluid.	12 ounces.

The hypertrophic capacity of the heart as representing visceral muscle appears to vary in different people just as does the hypertrophic capacity of the somatic general musculature. But we can all develop our muscles and perhaps all our faculties to some extent in proportion to the resistance we have to encounter, provided we put our backs into the business slowly, continuously, and systematically and do not rush at a task with delirious precipitancy. So also we find the influence of tethering conditions in pericarditis exerts a certain exaggerating influence upon cardiac hypertrophy apart from the native developmental power of a given patient. Thus, if we compare Cases 5 and 6 among those to which I have just referred we find that they were both females and both 11 years of age. Case 5 had mitral and aortic disease, with costo-pericardial, but not viscero-pericardial adhesion and her heart weighed 15½ ounces. Case 6 had only a mitral regurgitant lesion but there was much viscero-pericardial adhesion and also adhesion of the pericardium to the ribs and her heart weighed 25 ounces. Now this notable difference cannot be accounted for by the nature of the valvular lesion, for, *a priori*, we should have expected the additional aortic lesion to have tended to add to the hypertrophy of the heart, for it is in disease of this valve that we more frequently find the cor bovinum, other things being equal, than in cases in which the mitral valve alone is affected. It is, of course, possible that No. 6 had the greater hypertrophic capacity to which I have referred, but a more probable cause is the difference in the nature of the pericardial lesions. In Case 5 the heart moved freely within its sac. In Case 6 both systole and diastole were impeded, in addition to any endocardial valvular impediment to the blood stream. In Case 8 also the case of a girl, aged 13 years, with mitral reflux alone and a firmly adherent pericardium, the heart weighed 26 ounces; while in Case 10, a girl, aged 11 years, with mitral regurgitation but without pericarditis (the pericardium merely contained two ounces of static serum), the heart only weighed 12 ounces. These facts are sufficient to declare the aggravating influence of chronic adhesive pericarditis in heart disease.

---

[1] Heart Inflammation in Children, 1895, p. 5.

But when we consider the histology of pericardial inflammation we can see yet another source of deterioration in cardiac action due to that condition. In acute inflammation of the pericardium the stimulation of nerve trunks by the inflammatory process appears to be one of the causes of the disturbed action of the heart. I do not at present propose discussing this point in greater detail, in view of the prevalent myogenetic notions of some physiologists and physicians. For, insensitive as visceral nerves are in ordinary circumstances, we know that in conditions of disease pain may be referred to areas in which they are distributed and whatever the degree of independent muscular rhythmicality possessed by the cardiac muscle it is admitted that the heart is endowed with, and is under the control of, the nervous system. A specimen I place under the microscope shows how easily accessible cardiac nerve trunks are to spreading inflammatory processes in the pericardium. Under the external fibrinous layer of lymph a zone of active proliferation in the epicardium will be noticed. The invasion of leucocytes will also be observed at points to be creeping heartwards through the epicardial fat and at points of contact with the cardiac muscle interstitial proliferative processes will be seen in the latter. This section was made by me from the left ventricle of a girl who died in the Great Northern Central Hospital under the care of my colleague, Dr. C. E. Beevor. In more chronic conditions, with the thickening and organisation of interstitial carditis, muscle fibres degenerate and thus also some ultimate disability of the muscle cells is induced.

This pathological description applies to rheumatic cases in children which, as I have said and as Dr. Sturges pointed out, tend to become generally carditic. In these cases a so-called "simple carditis" may become "malignant" or "infective" or a malignant endo-pericarditis may be engrafted on an old heart inflammation of so-called "simple" character. Further discussion of these points would, however, rouse controversy which would lead us aside from our main theme —namely, the discussion of pericarditis in childhood as a clinical condition, practically considered. I need only add in this section that when extra-cardiac localised infections spread towards the heart and attack the pericardium the inflammation of the latter frequently becomes purulent, while, as I have stated, the endocardium and heart muscle as a whole escape.

The routine examination of the cardiac area at times leads to the early diagnosis of pericarditis. Thus a child was brought to me at the Children's Hospital, Paddington Green, on account of tonsillitis and the mother was unaware of any complaint beyond sore-throat. The tonsillitis was of the usual follicular type, but before dismissing the patient with a gargle and some salicylate mixture I placed the stethoscope over the heart and found general double friction sounds over the whole cardiac area. The child was at once admitted under my care to the hospital, when some effusion with increased cardiac dulness and diminished friction took place in due course. Although for a time there was noticed a soft apical bruit in the mitral area with triple rhythm, the patient was discharged recovered in about a month without any evidence of permanent endocardial lesion.

When there is evidence of general carditis with other rheumatic signs, pericarditis is not likely to be overlooked. Sturges points out that the fluctuation of percussion dulness at the *left* ventricular base—that is, at the level of the second and third left ribs—is the most trustworthy sign for determining variations in the amount of such pericardial effusion.[2] The effusion may be large and indicated by a much extended area of cardiac dulness with comparative inaudibility of heart sounds, or the distension of the sac may be too slight for detection at the bedside by clinical signs. Pericarditis is most likely to be overlooked when it is secondary to tubercle or pneumonia. In such cases the local conditions in the lung frequently appear sufficient to account for the state of the patient. In the absence of auscultatory signs of endocarditis the possible presence of pericarditis may not be suspected and is frequently only revealed after death. Thus a child ten months old admitted under my care at the Paddington Green Children's Hospital, exhibited a swinging temperature, dulness over the lower half of the right lung posteriorly, and an apex beat in the left nipple line, without noticeable bruit endo- or exo-cardial. The right pulmonary base was explored for pus, in view of the swinging temperature, on more than one occasion but without result. The child ultimately died. The lung was found to be in a condition of tuberculous consolidation, and the pericardium was full of a thin purulent fluid, while the surface of the heart exhibited the well-known shaggy appearance which has been termed cor villosum and is doubtless due to the movements of the heart within a cavity covered with recently effused lymph.

Passing from the diagnosis of acute to that of chronic conditions it might *a priori* be imagined that the detection of an adherent pericardium would not be an easy matter, except under certain well-defined conditions, and this is in practice found to be the case. Much ante-mortem positiveness, both for and against the existence of this condition, has been salutarily humbled by the revelations of the necropsy. But a justifiable surmise on this point may be made, as I have hinted, in certain circumstances. When the cardiac area is unusually large, the movements of the apex beat comparatively fixed in position on changing the posture of the patient to the right or left, and if, further, there be present a well-marked double bruit audible at the point of the heart we may be fairly certain of the existence of the condition in question, both as affecting the visceral and parietal layers of the pericardium and the tethering of the sac to the inner surface of the thorax. The double apical bruit in such cases appears to be due not only to incompetency of the mitral valve but also to some virtual narrowing of the atrioventricular inlet by approximation and fixation of the mitral curtains, caused by fixation of the ventricle, owing to pericardial adhesions. The recession of the intercostal spaces in the neighbourhood of the systolic apical impulse is not a trustworthy sign. It is no doubt witnessed when the heart is enlarged and the pericardium is adherent; but it is also seen when the organ is enlarged without being adherent. It may, that is, be due to negative pressure within the chest, not to active drag on its walls. A boy, aged 11 years, was admitted under my care to the Children's Hospital, Paddington Green, on July 24th, 1905, whose case is interesting and as it illustrates some of these points may be briefly related. He had suffered from rheumatic fever when six years of age and had been in other hospitals at that time, when his heart was known to be affected. On admission to hospital at the above date he had much dyspnœa, ascites, and œdema of the legs. The cardiac area was greatly increased, the apex beat being in the seventh space six inches to the left of the mid-sternum, and auscultation revealed an apical double bruit which was also audible in the back. The second sound was reduplicated and there was no sign of aortic valvular disease. Digitalis, strophanthus, and strychnine were prescribed in sufficient doses and 28 ounces of fluid were removed from the abdomen by paracentesis, after which his general condition improved. In August he was transferred to the Great Northern Central Hospital, still under my care, as the Children's Hospital was closed for cleansing. There his condition again became grave. The urinary output fell very much, his dyspnœa was urgent, and the pulse was quick; but under cardiac tonics and the steady administration simultaneously with these of opium he again improved and about the end of September returned to his own home much relieved as regards circulation and respiration but only so when at rest; any exertion still caused distress. He appears to have remained fairly comfortable at home until the beginning of December when his circulatory embarrassment again became great and he was readmitted to the Children's Hospital under my care on the 6th of that month. The physical signs were much as on admission originally but the liver was greatly enlarged and there was also again some ascites with considerable cyanosis. Although digitalin, strychnine, and morphine were used hypodermically and the patient was bled twice he gradually sank and died next day.

After death the heart was found to be greatly enlarged and weighed after the removal of all clots 21 ounces. The lungs were pushed aside and the external surface of the pericardium was extensively in contact with the thoracic wall and adherent to it. The visceral was likewise much, but not universally, adherent to the parietal pericardium. The heart itself was greatly dilated and hypertrophied, especially in its dextral chambers, and the tricuspid and mitral orifices admitted respectively five and four fingers, while the edge of the posterior curtain of the latter was slightly thickened. The pulmonary and aortic valves were competent and unobstructed. The other organs exhibited the usual phenomena of chronic congestion. The case was therefore one in which endocarditis, if present at all, had played a very subsidiary rôle. The large size of the heart, its comparative fixation in position, and the double apical bruit led to the surmise of adherent pericardium during life and the necropsy justified the belief. In the most marked cases, however, experience and the humbling revelations of the dead-house have taught us sufficient prudence to avoid positiveness in the diagnosis of many cases of adherent pericardium.

[2] Loc. cit., p. 35.

The *prognosis* of pericarditis in childhood is roughly indicated by the history of the three types of case which I have mentioned, although differences in detail may modify the destiny of sufferers even in these cases. There was: 1. The case of uncomplicated pericarditis with effusion following tonsillitis in which the heart ultimately returned, so far as clinical signs could determine the fact, to a normal condition. Cases are met with also of this type in which the issue, if ultimately favourable, is much more delayed. The effusion may be much greater and more persistent and even require surgical aid for its removal. When, moreover, such pericarditis is associated, as is often the case, with more serious implication of the myo- and endo-cardium the result, as we know, is too often fatal, the determining factor in such cases usually being the concurrent disease of more vital structures or the greater virulence of the infective state to which the local lesions, both endo- and peri-cardial, owe their origin. 2. The pericarditis of childhood associated with tuberculosis and pneumonia even without endocardial complication is always of grave prognosis and the tuberculous perhaps more hopeless than the pneumococcic. 3. Prognosis in adherent pericardium is naturally dependent largely upon the degree of symphysis within and outside the pericardial sac and, as I have stated, the determination of this point is by no means easy. The very hypertrophic capacity of the heart which favours the notable increase in the size of the organ in some of these cases seems to favour additional tethering impediment to cardiac action by bringing the sac into close contact with the heart and surrounding parts.

When pericarditis is, as is frequently the case, a secondary incident in a grave general infection and the degree of inflammation of the sac is moderate and non-purulent so far as clinical signs can reveal these conditions, while the amount of effusion is also not great, it will be well to remember the sage sarcasm of the able physician with whose remarks on the treatment of pericarditis I commenced this paper. The less it is treated as a separate entity the better. To add dermatitic discomfort by blistering to the general distress of the little patient in these circumstances seems wanton, because useless. When, however, inflammation of the pericardium is the initial event and there is reason to believe that the accumulated fluid is purulent in character, or its amount from physical signs great and in itself a source of danger to life, inactivity ceases to be masterly and interference by local methods not only justifiable but at times affording the only prospect of a successful issue. While the lines of general treatment remain the same, whether the pericarditis be associated with endocarditis or not, and are indicated by the nature of the infection and state of the heart and other organs, an early and non-purulent pericarditis may be treated by leeching, external warmth, or careful blistering like any other definitely localised inflammation. If purulent in character and recognised as such, or if large in amount and itself, as may be the case, threatening to life, the pericardial contents should be withdrawn by incision and drainage or by aspiration or trocar as may be indicated. As between these methods there can be no doubt that removal of a portion of parasternal cartilage, exposure of the sac, and careful incision or puncture would be a much safer and more scientific procedure than the blind puncture usually practised and which, as is well known, has on occasion proved immediately fatal by wound of the heart.

Dr. Samuel West relates a case of purulent pericarditis in a boy, aged 16 years, which was successfully treated by free incision and drainage[3] and also furnishes statistics of a considerable number of cases of serous, sanguineous, and purulent pericarditis surgically treated, some of which were in children.[4]

The local treatment of the chronic condition, the treatment of adherent pericardium is at present, and in some cases will always remain, outside the range of interference by local means. We have seen, however, that such adhesion is an aggravating incident in the carditis of children and apparently an incentive to cardiac hypermyosis, as I would suggest, we might term that degree of hypertrophy, which has been likened to the heart of an ox. As, moreover, we occasionally meet with cases post mortem which suggest that the adhesions might have been dealt with during life by surgical methods with comparative ease, we should not lightly dismiss the possibility of surgical interference in some of these cases. Could we discriminate these cases with some certainty during life it seems feasible that their treatment by surgical methods might remove one of the factors in the hypermyosis to which reference has been made and thus lighten the cardiac struggle without necessarily shortening the life of the patient. The point could, of course, only be fully determined by an exploratory operation as in other regions and carried further or abandoned as circumstances indicated.

I am aware that in speaking thus I do so on theoretical grounds and not from actual experience, but such thought has frequently preceded action ultimately justified by results, and I am not unhopeful that surgery, which has accomplished so much, may also in well-defined circumstances find a place in some cases of adherent pericardium. To return to our embryo, the growing organ requires a surplus of room to grow in; the overgrown organ requires more room to work in and it may be that tethered by extraneous adhesion, or not so restricted, the hypermyotic heart may in the future and in some cases be provided with such by the genius and courage of some surgeon bold enough to undertake the task. Human life is sacred, but not necessarily the pericardium, the division of which, with or without removal of ribs, might release, if only in a measure and for a time and even only in a few cases, an overgrown or overtaxed heart. I believe, however, that such a procedure would be justifiable more frequently than we are at present disposed to think. To the derision of a reviewer I advocated cardiac symphysiotomy some years ago[5]; but time was when opening the pericardium for any purpose whatever was regarded as unjustifiable. According to Dr. West[6] physicians such as Van Swieten and Laennec had to urge surgeons to perform even paracentesis pericardii and elaborated plans for its execution to induce them to act. Aseptic surgery should be able to go a step farther in this direction with less hesitation, and by releasing tethering and removing bone and cartilage provide the additional space which the enlarged organ demands for easier systolic contraction and which it gains at present by injuriously encroaching upon the territory of the lungs.

The consideration of the treatment of disturbances of cardiac action associated with pericarditis both acute and chronic does not strictly fall within the scope of this paper, but the general outline of treatment mentioned in connexion with the last case cited sufficiently indicates the mode of procedure and may serve to provoke discussion. I would especially call attention to the value of opium and of sufficient doses of the digitalis group in these circumstances. So long as a physiological antidote to the over-action of opium exists in the constitutional state of the patient, as manifested by violent and disordered action of the heart, usually associated with dilated pupils—the pupil of belladonna—children tolerate much larger doses of opium than is often supposed probable, while pushing the digitalis group, that is, carefully increasing their dose, frequently helps to steady a heart unaffected by smaller quantities of the same agents.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—A quarterly meeting of the Royal College of Physicians of Edinburgh was held on July 17th, Dr. John Playfair, the President, being in the chair. Dr. Andrew Balfour was introduced and took his seat as a Fellow of the College. Mr. Sydney Wilson Thompstone, M.R.C.P. Edin., Zungeru, Northern Nigeria, West Africa, was admitted by ballot to the Fellowship of the College. Dr. James Mair Rutherford and Dr. John McGibbon were admitted to the Membership of the College after examination. The Registrar reported that since the last quarterly meeting of the College 25 persons had obtained the licence of the College by examination. Dr. Francis Darby Boyd, C.M.G., was recognised as a lecturer on materia medica. The regulations regarding the Membership and Fellowship of the College for the ensuing year and the regulations for the triple qualification were approved.

APPENDICITIS AND GANGRENE OF THE VERMIFORM APPENDIX CONSIDERED AS SEPARATE DISEASES.[1]

BY JOHN D. MALCOLM, F.R.C.S. EDIN.,
SURGEON TO THE SAMARITAN FREE HOSPITAL.

THE object of this paper is to show that in a considerable number of cases of mischief connected with the vermiform appendix the initial lesion is a formation of a gangrenous patch in the wall of that part of the intestine, a condition which is frequently associated with an appendicitis beginning in the mucous membrane but which may arise independently.

Cases of appendicitis beginning in the mucous membrane.—In a very large proportion of cases the symptoms and the physical changes observed are easily understood as the effects of inflammation beginning in the mucous membrane and extending outwards in varying degrees. I have illustrated some of the conditions which may arise by short records of six cases.[2] I do not, however, propose to read these notes. All the patients recovered and there can be little difference of opinion concerning the relationship of the phenomena described to their causes. When the lumen of the appendix is quite open a continuous or repeated catarrhal inflammation induces an organic stricture and, if such a process begins at the tip, an obliteration of the whole canal may gradually take place without symptoms, the occluded appendix being discovered accidentally. On the other hand, when an inflammation of the mucous membrane of this tube is associated with an obstruction to the outflow of its contents the symptoms commonly attributed to an appendicitis develop. Recovery may follow so that no evidence of disease remains or after recovery is fully established from a clinical point of view the appendix may be found permanently dilated by muco-pus on the distal side of an incomplete stricture or peritoneal adhesions may alone indicate that previous mischief has existed. But an inflammation associated with an obstruction may bring about an extension of disease by ulceration of the mucous membrane and the ulcerative process may eat into, and penetrate, the wall of the appendix so that an abscess cavity forms in the adjoining tissues. This extension of inflammation is always preceded by a formation of serous adhesions, so that abscesses thus formed do not burst into the peritoneal cavity unless the parts are exposed to injury. A movement of the bowels may sometimes cause a sufficient strain to bring about a rupture but this rarely occurs. Two of my cases show that if the obstruction in the lumen of the appendix is relieved after an abscess has formed and if the abscess discharges freely through the appendix into the cæcum the patient may appear to recover, although a pus cavity still exists. One of the patients was sent to the country as convalescent and appeared to remain well for a fortnight, although she had an abscess as large as a pigeon's egg near the centre of her abdomen.

According to these views the importance of an obstruction in the lumen of the appendix as a cause of symptoms of appendicitis is very great. Indeed, it seems to me not too much to say that none of the ordinary clinical indications of this condition ever do arise unless the lumen of the appendix is obstructed. As in all other parts of the alimentary canal so in the appendix a catarrhal inflammation of the mucous membrane may be regarded as painless, unless its surface is stretched, or some obstruction to the muscular contraction of its wall exists and causes a colic. Similarly a catarrh of the appendix without retention of secretions rarely, if ever, induces a rise of temperature. Further effects of inflammation, such as sloughing, hæmorrhage, and the development of metastatic collections of pus, depend on the particular micro-organisms that are most active for mischief in individual cases. All the foregoing conditions are easily understood as the results of inflammation but there are other cases which require a different explanation.

Gangrenous changes in the wall of the appendix.—There are four conditions in which it is known that a local death of tissue may take place and may be unaccompanied by any clinical sign of the change except those which *follow* it. These are: (1) in senile gangrene; (2) in the case of a perforating gastric or duodenal ulcer; (3) in the wall of an ovarian tumour; and (4) in a fibroid uterine tumour. The evidence seems to me conclusive that a similar death of tissue may take place in a part, or in the whole, of the wall of the vermiform appendix without any indications preceding its occurrence. The cause of death in the conditions referred to is a matter of much interest but it has no bearing on my argument. The point is that a dead patch of tissue may exist whilst the individual appears for a time to be in perfect health and by this view it is possible to account for many of the phenomena connected with the vermiform appendix which are otherwise inexplicable. Case 7 is important in this connexion. The salient features of the history are as follows. A woman, aged 71 years, had a slight pain and tenderness about the middle of the ascending colon. After 30 hours there was some resistance over this part but the rest of the abdomen was soft and mobile. The temperature had gradually risen to 100° F., whilst the pulse was beating from 80 to 90 to the minute. The rectum was full of fæces and the bowels had not moved for two days. The patient did not appear to be seriously ill. No opiate was given. An enema was administered late at night and the bowels acted well. Next morning the conditions had altogether changed. The abdomen was immensely distended and very hard, the patient had been vomiting and retching for many hours, her pulse was 130, and she was obviously very ill, but there was no great pain, and the temperature was only 100·6° F. The abdomen was opened 44 hours after the onset of the illness. The vermiform appendix was situated outside the middle of the ascending colon. It was not adherent but was immediately surrounded by loose flaky lymph and the loin pouch contained a few ounces of slightly turbid serous fluid free in the peritoneal sac. The intestines were immensely distended and were emptied by incisions which were carefully closed but gaseous distension rapidly re-developed and death occurred early the next morning. The appendix had three well-defined gangrenous patches in its wall. These were not shrunken nor surrounded by a swollen or angry area and they were in continuity with the rest of the wall of the appendix, so that there was no rupture. The lumen was patent throughout and there was no stercolith.

This case suggested the view that I now advocate. It seemed that if these patches of dead tissue were the results of an inflammation there should have been a rapidly advancing high fever, continuing for some days before it terminated in gangrene, and all the parts around, not only in the wall of the appendix but also in the adjacent structures, should have been very vascular and œdematous. But evidences of an acute inflammation were wanting, whilst the symptoms and physical conditions may be fully explained as consequences of the passage of slightly irritating organisms through the patches of dead tissue *after* these had formed. Thus a spreading peritonitis of little virulence, causing a sero-purulent exudation, was first excited. An escape of greater numbers of the microbes or perhaps of some different micro-organisms accounted for the development of flaky lymph. Paralysis of the bowel with symptoms of intestinal obstruction and of septic infection inevitably followed, and the rapid pulse was due to the vomiting and general weakness. This case brought to my recollection one (Case 8) which came under my care ten years ago and in which the phenomena were exactly the same in many details. But in Case 8 the patient had long been subject to attacks attributed to pelvic inflammation and her last illness was ushered in by very severe pain. This initial symptom was probably due to a distension of the appendix. It is obvious that a stretching of a living tube, containing a gangrenous patch in its wall, must cause intense pain by dragging on the tissues adjacent to the dead area.

In these two cases the evidence that the gangrenous change was not due to an inflammation depends on the fact that the necrotic patches existed although signs of inflammation of sufficient intensity to be accompanied by a death of tissue were wanting. Other conditions point with equal certainty to the conclusion that gangrenous areas may develop without preceding symptoms. Dr. Howard Kelly and Dr. E. Hurdon quote two cases operated upon by Finney, in one of which the appendix was removed within three hours of the apparent onset of mischief and it was "gangrenous on one side and ready to perforate." In the other case, that of a young physician, the operation was performed within six hours of the initial complaint and "there was every reason to believe that the very first pain he felt was occasioned by the perforation."[3] Both cases recovered. There can be no doubt that in these cases the death of a patch of tissue in the wall of the appendix had occurred before there were any symptoms and that for a time the patients were apparently quite well, although in each a portion of the appendix was dead.

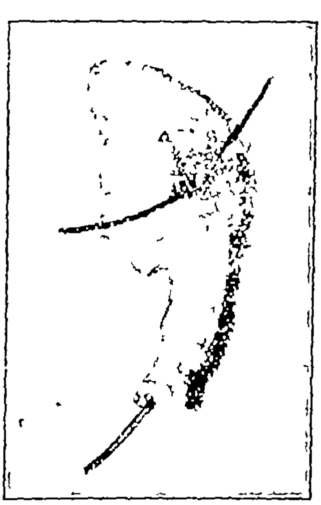
---

[1] Abstract of a paper as read before the Royal Medical and Chirurgical Society on June 26th, 1906.

[2] Three of these are published in full in the Clinical Journal April 11th, 1906) and in the Brit. Med. Jour. (July 14th, 1906, p. 71).

Spontaneous recovery from localised gangrene of the appendix.—It is difficult to understand how an area of necrosis in the wall of a hollow viscus can prevent an escape of infective micro-organisms until it has become so loosened that a gross perforation suddenly takes place, but the following cases throw light on this point. In Case 9 the patient, a woman, aged 58 years, was operated upon 19 days after a severe attack attributed to appendicitis began. Convalescence was thought to be thoroughly established, febrile symptoms and abdominal distension having subsided and the bowels being moved by purgatives without inconvenience. The appendix was universally adherent, chiefly to small intestine, but the attachments were easily separated by the finger as if the adhesions had just formed. The appendix had two holes in its wall close together, one being of oval shape and nearly half an inch long and both being surrounded by granulation tissue (Fig. 1). The small intestines were extensively adherent and on disentangling the coils two were found more firmly united than the others but still quite lightly attached. On each there was a granulating surface, the two making an area which had evidently been fitted upon the openings in the appendix. When the granulating surfaces were cut off and the raw tissues were sewn over the rest of the intestine showed hardly any sign that it had been adherent. There was no visible pus and the lumen of the appendix was not distended. The appendix was removed, the abdomen was closed without drainage, and the patient made a good recovery. Case 10 was in all essential details the same as Case 9 but the appendix lay outside the cæcum and there was a partial obstruction in its lumen, the distal part being distended by mucus, not by pus.

FIG. 1.



Appendix removed 14 days after recovery from an inflammatory attack. The openings were closed by adherent bowel. The proximal opening measured nearly half an inch by a quarter of an inch (see Case 9)

In each of these cases the patients appeared to be quite well when a perforation with loss of tissue of the wall of the appendix existed, the opening being sealed over by adherent peritoneum. If the development of these conditions had been caused by an ulcerative inflammation it would have been accompanied by the formation of a considerable abscess walled in by firm adhesions. Each of the patients undoubtedly passed through an inflammatory attack exactly simulating an appendicitis, but in each an obvious perforation without an abscess was found. Clearly an inflammation extending from the mucous membrane did not account for the phenomena observed. All the symptoms and pathological changes may, however, be fully explained in the following way. A gangrenous patch formed and the appendix became lightly adherent to adjacent peritoneum, either because of the escape of microbes which caused an adhesive exudation or because of the mere presence of the dead tissue. After a time the slough separated, became disintegrated, and was discharged through the appendix. Inflammation accompanied the separation and continued until a granulating surface formed and all tension ceased. But the inflammation affected that part of the peritoneum and that part of the wall of the appendix which had been adjacent to, and attached to, the dead patch, and its origin was therefore quite different from, and should be clearly separated from, that of an inflammation commencing in the mucous membrane. It is obvious that if in either of these cases a sudden increase of pressure had arisen within the wall of the appendix the adhesions would have been very easily broken down. In the case (No. 10) in which the appendix lay outside the cæcum the adhesions were so extensive and so well supported by the natural pressure of the cæcum against the abdominal wall that a localised abscess would probably have formed. Such an abscess when fully developed would exactly resemble one arising from an extension of inflammation from the mucous membrane by ulceration. In the case (No. 9) in which the perforation was closed by very slightly adherent coils of small intestine any considerable pressure within the appendix might have given rise to a rupture into the peritoneal cavity with a free escape of mucus and perhaps of fæces. Such a rupture might be accompanied by very acute symptoms, without preliminary warning, when the phenomena observed in Finney's cases above referred to would be reproduced But the rupture might be preceded by evidences of an inflammatory attack beginning in the mucous membrane as in the following case.

In Case 11, a woman, aged 37 years, had signs of a severe intra-abdominal inflammation, the temperature rose to 103·5° F., the pulse to 140, the abdomen became very hard and greatly distended, and the patient vomited frequently. I saw her in consultation after 36 hours. At that time the conditions were all improving, the sickness had stopped, the bowels had moved, and much flatus had passed and continued to be expelled through the rectum from time to time. The abdomen was quite soft and mobile, there was no pain, and I did not detect any tenderness except when I pressed on the neck of the uterus which had been curetted some months earlier. The temperature had fallen to 100° F.; the pulse was still as high as 130 but of fairly good quality. I thought the patient was recovering from the effects of over-indulgence in indigestible food. I did not see her again but I was informed that the conditions remained much the same for about 20 hours and then all the unfavourable symptoms returned and the patient died 12 hours later. At the necropsy two ruptures were found in the appendix, one having sloughy edges, and much fæculent matter had escaped. It seems to me that in this case the patient's condition had greatly improved when I saw her, because she was recovering from an attack of inflammation beginning in the mucous membrane of the appendix and that afterwards a gangrenous patch separated from the wall of this tube, adhesions which had formed gave way, fæculent matter escaped, and the patient rapidly died.

Conclusions as to the results of gangrene formation.—From the foregoing considerations it would appear that gangrenous patches forming in the wall of the appendix may bring about three well-defined conditions which are easily understood and are quite independent of inflammation beginning in the mucous membrane, although this also may be present. First, there may be an escape into the peritoneal cavity of micro-organisms which excite a serous, a sero-purulent, or a purulent exudation unlimited by adhesions. Second, the adjacent peritoneum may become adherent over a gangrenous patch and the latter separates and is discharged through the appendix, recovery taking place. Third, a gangrenous patch may thus become sealed off, but when it separates the adhesions also give way and a localised abscess forms or a rupture into the peritoneal cavity takes place. As the pathology and the consequences of gangrene formation are so different from those of inflammation beginning in the mucous membrane it is necessary that the two conditions should be clearly differentiated from a scientific point of view and as much as possible in practice.

---

[3] The Appendix and its *Diseases*, by Dr. Howard Kelly and Dr. E. Hurdon, p 408.

The numbers of the cases of localised gangrene of the pendix.—These cases are very rare in proportion to the umber of cases of inflammatory mischief in the appendix ut they bulk very largely in the death-rate. Dr. elly and Dr. Hurdon found that out of 4028 necropsies three large hospitals there were 86 cases in which eath was due directly or indirectly to acute inflammatory disease of the vermiform appendix. Of these 6 deaths, "in 29 cases there was acute gangrenous ppendicitis with single or multiple perforations. In two of hese a gangrenous appendix had entirely sloughed away rom the cæcum." "In 25 cases inspection of the bdominal cavity at the time of the autopsy revealed no ign of any tendency towards limitation of the inflammatory rocess to the immediate vicinity of the appendix, nor was here anything pointing to a previous abscess in the region f it."[4] Probably in all these 25 cases death was due to angrene formation. But, as I have pointed out, there is eason for believing that in some cases a localised abscess nay develop around a gangrenous perforation. The deaths lue to gangrene may therefore be considerably more than 25 ut of 86; yet even if these figures indicate the full numbers of such cases the condition must be regarded as a very mportant one

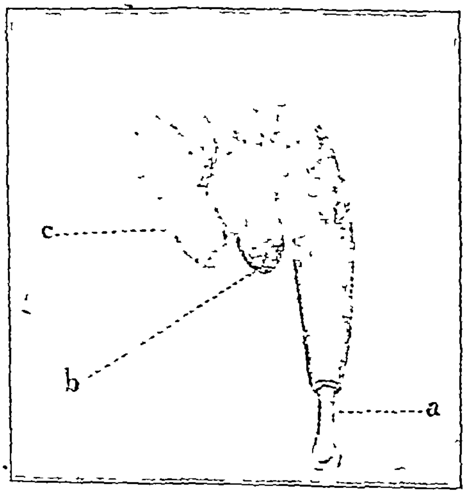
Diagnosis and treatment.—If we could make an exact diagnosis between the signs and symptoms of inflammation of the appendix beginning in its mucous membrane and those of the gangrene formation which occasionally occurs in its walls the treatment would be much simplified, but the differential diagnosis may be very difficult.

There are various indications of danger and rules of treatment which should be kept in view. The administration of opiates should be avoided if possible. On the other hand, laxatives and enemata may effect a cure and may be administered early in cases of inflammation, but they are contraindicated when gangrene exists. Hence whenever they are given in a case of appendix mischief preparations should be made for an immediate operation if urgent symptoms develop. In cases of very insidious onset a purge may prove beneficial by hastening the development of symptoms indicating the necessity for operative treatment. Nothing can be gained by watching such a case as No. 7 above recorded, even when the symptoms show no urgency Paralysis of the intestine is the most certainly fatal complication of an abdominal disease and every endeavour should be made to anticipate its onset by operative treatment in appendix cases. But the differential diagnosis between cases in which a gangrenous patch is present and those in which an inflammation spreading from the mucous membrane exists is often so uncertain that the propriety of operating in every case in which appendix mischief is diagnosed must be considered An operation for the removal of an inflamed appendix, if undertaken before septic mischief penetrates its wall and when the patient is suffering from a first attack, should be one of the safest in surgery. But when old adhesions exist great difficulties and dangers may arise from an attempt to remove the acutely inflamed appendix. Such cases would, of course, be practically eliminated if all were operated on early or in the first interval, a course which would lead to the saving of many lives. There would still, however, be a number of unrecognised chronic cases becoming acute and also of those in which the patients refused operation during an interval. Hence the surgeon is liable to meet with circumstances in which if he operates and finds many old adhesions he can only remove the appendix with great danger to the patient who may be in no fit state to undergo a serious operation, whereas if he does not operate and the patient happens to have a gangrenous patch infective mischief may rapidly obtain such a hold on the peritoneum that no treatment will be of any use. There can be no doubt, however, that the majority of cases of appendicitis recover without an operation being even thought of, and cases in which mild but decided febrile symptoms develop along with a well-defined localised swelling may be watched with little anxiety. On the other hand, in cases of gangrene formation with a sudden gross perforation the onset of the illness may be so acute that an immediate operation is clearly indicated, and Finney's cases show how successful this treatment may be. There are, however, many cases in which both inflammation and gangrene formation occur and the two conditions seem to be frequently related in such a way that the signs of the inflammation are subsiding when those of gangrene formation develop. In this way an adequate explanation is afforded of the "period of repose" so frequently observed in these cases. Hence, assuming that there are sufficient grounds for definitely diagnosing an appendix lesion, all cases beginning very acutely or in which urgent symptoms suddenly develop should be operated on immediately

When there is any doubt as to the course to pursue the case must be considered with great care and probably more harm will be done by unwisely avoiding an operation than by a *too* active treatment, provided, of course, that the procedure is carried out with reasonable discretion and consideration. I would urge, however, that the difficulties and dangers do not arise so much from an appendicitis as from the fact that the patient, or even an individual who appears to be in perfect health, may have a gangrenous patch in his appendix causing no symptoms whatever, but which after a time, either slowly or with the greatest rapidity, may induce conditions that terminate certainly in death. The fact that a sufficiently early operation will bring about the recovery of a large number of patients in these desperate conditions is a strong argument in favour of prompt interference.

Case 12 suggests a line of treatment that may occasionally be desirable. The abdomen of a lad, aged 18 years, was opened during an acute appendicitis but the operator did not remove the appendix because of its close attachment to the bowel, the inflamed and softened condition of the parts, and the state of the patient. A tampon was inserted and recovery followed without pus formation. The difficulty was due to a previous attack 12 years earlier. The operation was performed abroad by an experienced surgeon and when the patient was quite well I successfully removed the appendix. It was acutely bent near its tip (Fig. 2) and there was a constriction about half an inch from the cæcum so narrow that a bristle would not pass. The part between the bend and the constriction was distended by a thick yellowish fluid. A point of interest in this case was that there were five or six lymphatic glands, some of them half an inch long, clumped together close to the appendix. It would appear that this quite unusual arrangement had been produced as a defence against the invasion of bacteria. Obviously a source of danger had existed from the date of the first attack at the age of six. There is no doubt that it was wise not to remove the appendix when the abdomen was first opened, for the operation which I performed would have been extremely formidable if the circumstances had not been favourable. Certainly it would be better occasionally to undertake two operations as in this case than to delay interference and to miss the opportunity of curing a patient with a gangrenous patch, or to persevere with an operation in order to obtain an immediate success under desperate conditions when a safer,

FIG. 2



Appendix from Case 12. a, Constriction, b, tip; c, glands (several were separated during the operation) although less brilliant, method is available. In the circumstances of this case the absolutely essential part of the operation is to ascertain if a gangrenous patch exists. If there be no such lesion the removal of the appendix is not urgently called for, but, as a rule, its excision will be easy and should be accomplished. When difficulties are great it may be wiser that drainage should be provided for and that the appendix should be left for the time. To discuss the propriety of these proceedings involves a confession of inability to make an exact diagnosis, but if the view I advocate is correct it is certain that an urgent necessity for operative treatment may arise in connexion with the vermiform appendix before there are any symptoms at all. The conclusion that a most serious condition may exist when a diagnosis is impossible does not seem to be very helpful, but a recognition of this fact enables us to understand much in these cases that cannot be otherwise explained and to understand a condition is the first step to its rational treatment.

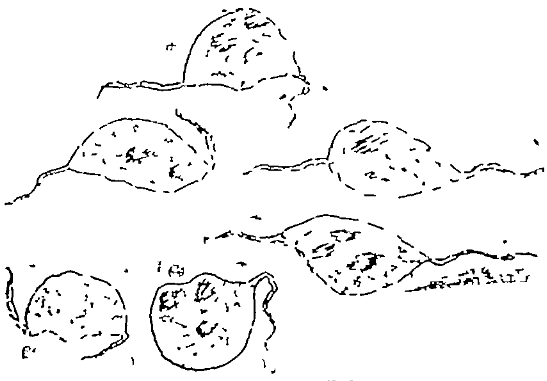
FLAGELLATED PROTOZOA IN A PERINEAL ABSCESS.[1]

BY E. HENDERSON HUNT, M.A., M.B., M.CH. OXON., F.R.C.S. ENG.,
MEDICAL OFFICER TO H.H. THE NIZAM'S GUARANTEED STATE RAILWAYS COMPANY, HYDERABAD.

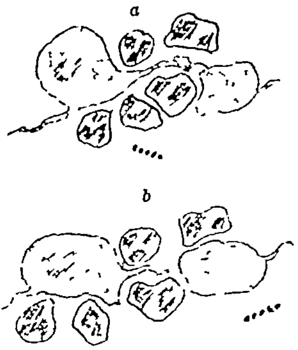
THE patient, a Eurasian, aged 48 years, was admitted to the Railway Hospital on Dec. 16th, 1904, complaining of a "pressure pain" in the pelvis and difficulty in micturition and defæcation, which had commenced three days before. He had formerly been in many countries, including England, Egypt, &c., while working as a marine engineer. Apart from gonorrhœa in 1890 and malaria in 1903 he had always been healthy. He had never passed blood or pus in his urine nor had he suffered from any rectal troubles. He remembered swallowing a fish bone a few weeks before admission to hospital. On admission the patient looked ill, the temperature being 101° F. and the pulse 110. The lungs and heart were normal as also was the urine. In the blood no malarial parasites were to be seen but there was a slight leucocytosis, chiefly multinuclear. Per rectum a hard tender lump was felt in the region of the prostate. The patient was watched and on Dec. 22nd the lump became suddenly larger and with two fingers in the rectum fluctuation was detected. A deep incision was then made in the perineum and a cavity was opened containing about an ounce of pus and much evil-smelling gas. This cavity was at a considerable depth from the surface, in front of the rectum, and apparently between the layers of the triangular ligament. The urethra, the prostate, and the bladder seemed to be in no way involved. The pus was examined fresh at once. Swarms of very active streptococci in long and short chains were seen. There were also large numbers of flagellated bodies, each rather larger than a pus cell. These presented a very striking appearance from their extraordinary activity. They were more refractile than the pus cells. The outer coat was very thin and easily protruded when the organism came in contact with pus cells. At first two or three darker masses were seen inside resembling nuclei. The rest of the body was filled with fine granules. The flagella were two, situated nearly, but not exactly, opposite each other. These moved freely and seemed to pull the organism along among the pus cells. The pus was placed in a warm chamber and after six hours most of the flagellated bodies had become circular and looked much smaller. The flagella were shorter and difficult to see. The movements were almost purely rotary but still rapid, numbering as an average 20 complete turns in 15 seconds. Those which had become stationary were difficult to pick out among the pus cells. When living they resisted taking up weak stains which coloured the pus cells well. It was remarked that the rotation was invariably in one direction, the apparent movement being as the hands of a clock. In no stained specimen could this organism be seen. Various methods were tried but all were equally useless. The urine and fæces were examined but no similar bodies were seen.

FIG. 1.



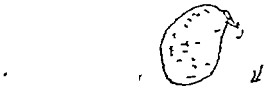
Six fresh specimens. $\frac{1}{12}$th. Flagella long and very active

FIG. 2



a and *b*, Fresh specimens $\frac{1}{6}$th. Showing differences in shape after an interval of a few seconds.

FIG. 3.



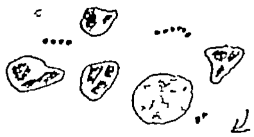
$\frac{1}{12}$th. After six hours. Rapid rotation. Short flagellum seen.

The patient made a rapid recovery and the wound closed as soon as the drainage-tube was taken out. He himself gives as the cause of his trouble the fish bone which he remembered swallowing. The situation of the abscess would certainly be compatible with this, for the prostate and urethra seemed in no way involved. The *flagellated* bodies might perhaps have been present in the rectum and, either by means of the fish bone or some other agency, have reached the tissues outside. The smell of the pus strongly suggested bacillus coli communis but none were found either in film preparations or in cultures.

This case shows the importance of examining pus immediately and alive. It is impossible to detect such protozoa in specimens prepared by any of the ordinary stains. It may well be that such protozoa play an important and unsuspected rôle in the causation of many forms of suppuration and that their presence is not detected owing to the fact that the methods commonly used in the examination of pus are not suitable for their demonstration.

Secunderabad.

FIG. 4.



After six hours Showing the relative size of pus cells Rotation rapid in the direction of the arrow. $\frac{1}{6}$th. No flagella visible.

---

[1] For various inevitable reasons there has been much delay in the publication of Dr. Henderson Hunt's interesting note.—ED. L.

A FEW SUGGESTIONS FOR THE FUTURE OF CONSUMPTIVE PATIENTS OF THE WORKING CLASSES.

By M. S. PATERSON, M.B. Durh.,
MEDICAL SUPERINTENDENT, BROMPTON HOSPITAL SANATORIUM, FRIMLEY;

AND

F. C. SHRUBSALL, M.D. Cantab.,
RESIDENT MEDICAL OFFICER, BROMPTON HOSPITAL.

AT the present time, when so much attention is being paid to the provision of proper facilities for the treatment of tuberculosis among all classes of the community, how best to advise consumptive patients after such treatment as to their future career is becoming more and more a matter for earnest consideration.

The initial requirements are known to all and indeed are obvious. Each individual should be placed under medical supervision at a sanatorium or under similar conditions at home if he can afford to pay for treatment. If unable to do so he should be sent to some institution, whether a chest hospital or a sanatorium, more or less supported by voluntary contributions. If ideal conditions prevailed he should remain therein until either the disease were arrested or he were released by death. This, however, is not at present practicable, partly on account of the paucity of such institutions and the insufficient support rendered to those that are actually in being, and partly from the necessity for material aid to tide the family over the period during which the bread-winner is undergoing treatment and education, a purpose for which no due provision has as yet been made. The best that can at present happen is for a patient to be sent to some institution for a time, rarely exceeding nine months, during which, if he is fortunate, his disease becomes more or less arrested, and he is instructed in healthier modes of life and how to take precautions to avoid being a source of risk to others. Even among those who can afford in some measure to pay for treatment a long course is rarely possible, for when both the patient and his household have to be supported on a diminished income reserve funds are rapidly exhausted. Also a patient's occupation can seldom be kept open for an indefinite period, so that the individual has to choose between returning to work, it may be somewhat prematurely, and seeking fresh employment after a longer convalescence, with the prospect of a diminished wage and lost opportunities for promotion. Recognising, then, the imperative necessity for each patient to earn his own living the question to be considered is the nature of the employment he should seek. We all know the ideal; what is needed is a practical solution of the difficulties that confront us.

It would appear that sufferers receive advice and suggestions of the most diverse and often unpractical nature from all who come in contact with them. Even members of the medical profession cannot be entirely absolved from the charge of at times giving advice hastily without considering the occupation, ability, and financial position of the individual patient, which are probably of more importance in this connexion than the actual extent of his disease. It is a constant experience on inquiring what a patient proposes or hopes to do on leaving a chest hospital or sanatorium to obtain such answers as: "I have been told I must get light open-air work" and "I have been advised to live in the country." Others appear to have received the impression that they should take up gardening as a means of livelihood, or go for a voyage as a ship's steward, or emigrate to Colorado, the Cape, or Australia. So frequently does this occur that doubts arise whether those who give the advice in any degree realise what they are recommending.

The natural inquiry to follow the narration of any of the foregoing suggestions is, "Have you a trade and, if so, what can you earn?" A large proportion of hospital patients are unskilled labourers but when such a one has a trade it may be found that he earns £2, at times perhaps even £3, a week. If he be then further asked whether he has any skilled knowledge of outdoor work, it almost invariably appears that he has not and that some 15*s*. to £1 a week is all he could hope to earn in very favourable circumstances. Whether, then, is it wiser for that man to return to an occupation at which he has a definite market value or to go out among the flotsam and jetsam of unskilled, often unemployed, even though nominally open-air workers? Two points have to be borne in mind—the safety of the community and the welfare of the individual. As regards the former, it may be affirmed that there is no risk apart from the drying up of expectoration which allows the living bacilli to be blown about as dust. Fraenkel's recent work has shown that the risk of infection, even in the immediate proximity of the patient, from the spray inevitably produced by coughing is so small as to be nearly negligible, and, indeed, were it not so it is difficult to see how the *personnel* of a hospital for consumption could reside therein for years and yet remain free from the disease.

The extreme popular view of the contagiousness of consumption with the naturally associated tendency to treat all sufferers as lepers is unjust, unwarranted, and an economic error. It may be that the disease in any individual has been arrested, that he has no expectoration, or if any that it has by repeated examination been found to be free from tubercle bacilli; such a person could with safety to others be sent to work in any surroundings. Even a quiescent case who has not advanced so far towards recovery is of very little danger, provided that he has been educated to use a sputum flask and can be trusted not to spit about or let his expectoration dry but to attend to its safe bestowal—that is, if he is an ordinary careful intelligent human being. It is also to be remembered that an arrested case of pulmonary tuberculosis returning to an indoor occupation will be an apostle of the advantage of leading a better hygienic life and so should by his example and precept tend towards diminishing the prevalence of the disease.

For the welfare of the individual the most important considerations are the provision of fresh air at home, good food, and reasonable hours and conditions for rest; in other words, an ordinary healthy life out of working hours. This can only be obtained at a price, hence the necessity to earn the best possible wage. No amount of fresh air during work will compensate for the lack of sufficient nourishing food or bad accommodation during the rest of the day; there is a certain tendency to forget that starvation is a more serious trouble than tuberculosis.

Two of the greatest risks to the patient whose disease is arrested are overstrain and great fatigue which appear to have a very special influence in bringing on a recrudescence. From this standpoint it would seem preferable that any patient who is a skilled workman should return to his former occupation, for what can be done with facility will be done with the least unnecessary expenditure of energy. The hardest and most continuous manual labour usually falls to the lot of the unskilled labourer, such as any artisan would become should he leave his trade. Although it has been shown by sanatorium experience that those who have led sedentary lives are capable, despite their affliction, of being trained up to do hard manual labour to their physical benefit and without any harm soever resulting, this is only because the hours of such work are regulated and periods of rest interposed in a manner impossible in everyday life. We do not by this mean to suggest that manual labourers accustomed throughout their lives to such toil cannot return to their occupations, but rather the contrary, since such work comes easier to them.

From the statistics of the German sanatoriums it would appear that cases discharged as quiescent or arrested are capable of returning to their former occupations for periods of three, four, or more years and nowhere are there any definite facts to show that this is not equally possible in this country. An arrested case should be safer, whatever his occupation might be, than he was before he acquired his illness, since he has learnt how to live in the healthiest possible manner For the same reason a quiescent case should be no worse off than before.

Fresh air throughout the whole day is no longer so essential once the processes of disease have become quite quiescent. Less good air will then suffice for a time provided it be not absolutely deleterious, and if it be it is wrong that anyone should work under such conditions. The skilled man who at his own trade could earn a fair competence would have to work longer hours and at a greater strain in an outdoor occupation for a wage which would scarcely support life, since he would have to compete in the labour market against those who, having been born and bred to the work, would naturally secure all the better posts. The problem of the clerk, shop-assistant, and warehouseman must be considered in the light of the same reasoning—the relative economic value of his work, his wage earning capacity in relation to the cost of living, and his surroundings when off duty. He must earn sufficient to enable him to procure reasonable conditions out of working hours. Vanmen, tram and omnibus drivers and conductors, and most classes of railway servants could not do better than remain at their occupations. As regards the unskilled labourer there is no *a priori* reason why he should not go into the country to look for work but in recommending such a course it must be remembered that this is very difficult for even a perfectly healthy man to obtain.

It should not be forgotten that many patients suffering from pulmonary tuberculosis in a more or less active stage, often with tubercle bacilli in their sputum, remain at in-door work, at the same time attending the out-patient departments of our hospitals. It must be the experience of many that these individuals continue to work under such conditions for many years, so that there is a reasonable prospect that had they had the advantage of the hygienic education and the improvement of their general health, to say nothing of some degree of arrest of the primary disease which would have followed in-patient treatment, they might have remained self-supporting for an indefinite period.

The alternatives to following his own trade usually suggested to a patient, as we maintain frequently without due consideration, are: (*a*) to obtain some open-air occupation, preferably in the country, in which case gardening is usually recommended; (*b*) emigration; and (*c*) going to sea. These may be briefly dealt with *seriatim*.

(*a*) Many patients shortly before their discharge from hospital talk of looking for some such open-air occupation, but on being pressed appear to have no idea what variety of work they require nor how to proceed to find it. From the stories of patients re-admitted to hospital after some lapse of time it appears that if they have remained in town a large number have become tram and omnibus conductors, frequently with good results. This course, however, cannot be recommended save to those with little or no expectoration, since a man making use of a spitting flask would almost certainly be complained of by some zealous passenger and would stand little chance of obtaining further employment. The wages earned are also not excessive. In spite of these objections this occupation is one of the most suitable for an unskilled patient. Others have tried to serve as insurance agents or travellers on a small scale. These more often than not have proved failures both economically and medically. Want of knowledge of their business has prevented their earning enough to live decently and at the best an agent's life about town is far from being in the open air but rather involves the risk of exposure to all kinds of infection in the houses he must visit. Also it is our experience that there is a tendency for such men to indulge too freely in alcoholic stimulants, a course productive of great evil in cases of pulmonary tuberculosis. Patients but rarely appear to have endeavoured to act as gardeners for obvious reasons. If more than a mere pittance is to be earned some degree of technical skill is required, to acquire which a proper apprenticeship must be served. It is as absurd to expect an untrained patient at once to become fit for such an occupation as it would be to advise him to act as a fully trained druggist. Another feature which militates against gardening as a suitable trade for consumptive individuals is that to earn a fair wage a gardener must have a knowledge of, and carry out, hot-house work, whereby he runs grave risks of catarrhal attacks which probably predispose towards a recrudescence of the pulmonary tuberculosis. For the beginner employment is uncertain and the accommodation for the labourer and his family is often of an unsatisfactory nature. In addition to which it is improbable that in the country the other members of the family would be able to do much to add to the income, and if they are dependent on the patient as sole bread-winner their fare will be scanty.

(*b*) Emigration opens up still more serious problems. When a patient seeks advice on this subject the most important question to ask is, Has he definite employment to go to and, if so, are the wages such as reasonably to support him under the prevalent local conditions? Failing work, definitely arranged for in advance, has he friends to stay with who will keep him until he can obtain employment? Also, Has he a knowledge of any trade or other occupation for which there is a demand? If these questions be answered in the negative such a patient should be advised not to go, however much a climatic change might be expected to benefit him. His health might not improbably suffer on the voyage and his slender capital be rapidly exhausted while in search of employment. Everyone who has been to the colonies must have seen some such half invalids reduced to extremities. It is often overlooked in England that it has been found necessary to establish sanatoriums in South Africa, Australia, and Canada, the very places to which our consumptives are advised to emigrate. To emigrate with inadequate means and without definite prospects is a task not lightly to be undertaken successfully even by those in perfect health and with some useful knowledge; far less, then, by one town-bred, just recovering from a severe illness and without experience of outdoor work. If, however, the patient has a post offered him in advance or friends to go to his state of health can be considered in relation to emigration. Should his disease be arrested no obstacles need be placed in his way other than to warn him that he is going far from home and may be in difficulties should he relapse. If the disease be only quiescent the case must be put much more strongly and the patient should thoroughly understand the meaning of the risks which he incurs. The conditions thus far being satisfied inquiry may be made as to where he proposes to go. Many patients will be found who have the haziest notions of geography and believe that all places out of England are health resorts. They believe the supposed climate is everything and are unaware of the distances and variations met with in all the colonies, the United States, and the Argentine, many parts of which are climatically inferior to England. They cannot realise that Northern Territory is not Darling Downs, Durban not the Drakensberg or the Karroo, Quebec or Chicago not the slopes of the Rockies; that it is not as healthy to serve in a store at Denver as to be ranching, to tend behind a bar in Johannesburg as to farm. Lastly, the economic aspect should be again clearly placed before every patient desirous of going abroad, since many deceive themselves as to the relative value of wages. Especially is this the case with regard to Johannesburg, where all the necessities of life are so much dearer that even with better wages many—nay, most—artisans write home that they are really worse off than in England and in some cases though in full work find themselves without sufficient money to procure proper food.

(*c*) Going to sea is perhaps less frequently advised than a few years back. Most patients who mention going to sea propose to do so in some working capacity. This on investigation resolves itself into seeking a berth as ship's steward or, in the case of clerks with somewhat better attainments, as a purser's assistant. Now, however much, or little, open air a passenger in a liner may secure neither of the above categories could be described as sharing therein. That all who go to sea spend their time on deck fanned by appetising salt breezes is a pure popular delusion. The purser's assistant usually spends his days in a small, very stuffy cabin whether at sea or in port; his nights under similar conditions. The steward lives in still worse quarters—crowded out, heavily worked, with few opportunities for sleep, and in the tropics the chances are poor enough for anyone. At the beck and call of everyone, with little time off duty, he lives practically between decks in adverse circumstances everywhere and always. The popular idea is that stewards, however bad their quarters—and they are usually so near the water-line that the scuttles can never be opened—have always the opportunity of sleeping on deck. Now, in bad weather, when their quarters are naturally at their worst, this is obviously impracticable. As tuberculosis is far from uncommon among ship's stewards anyone following this occupation must pass his time of rest in an ill-ventilated and infected atmosphere. This is the more so as any one desirous of keeping his berth would be unable to use a spitting-flask, which would be detected, and so must either swallow his expectoration at his own risk or use his handkerchief, to the risk of others when the sputum dries and the bacilli escape as dust.

Our conclusion is that so far as possible each individual should return to his own trade and that those without a trade should be largely governed in the selection of an occupation by their wage-earning capacity thereat. If the only result of the treatment of pulmonary tuberculosis be the production of large numbers of unskilled outdoor labourers can this be considered an economic success? The matter is one over which there must obviously be some difference of opinion and we set forward our views in the hope that they may at least draw attention to the subject and so help the unfortunate consumptive to be advised thoughtfully as to his future.

THE PASSAGE OF SPIROCHÆTA DUTTONI FROM MOTHER TO FŒTUS.

BY ANTON BREINL, M.D.,
ASSISTANT LECTURER IN TROPICAL MEDICINE, LIVERPOOL SCHOOL OF TROPICAL MEDICINE;

AND

ALLAN KINGHORN, M.B. TORONTO,
JOHNSTON COLONIAL FELLOW, UNIVERSITY OF LIVERPOOL.

(From the Runcorn Research Laboratories of the Liverpool School of Tropical Medicine.)

IN a publication on *Spirochæta obermeieri* Albrecht states that he found the parasites in four fœtuses, seven months old, from mothers who were suffering from European relapsing fever. Spitz made a similar observation in the case of a five-months' fœtus, finding the parasites in an intracranial hæmorrhage. In our experimental work on *Spirochæta duttoni*, the organism of African relapsing fever, we have been able to demonstrate the passage of the parasites from mother to fœtus in the case of four rats and one guinea-pig.

Experiment 1092 C.—Rat inoculated on April 3rd, 1906, with heavily infected blood. After showing spirochætæ for 16 consecutive days it was killed for subinoculation. The heart blood showed from 20 to 30 parasites to a field (Zeiss $\frac{1}{12}$ oil immersion, No. 4 ocular). The heart blood of three half-grown fœtuses and that of their placentæ were examined with the following results:—

Placenta I., 1 to 2 spirochætæ per field: Fœtus I., 1 spirochæta to film
„ II., 6 „ 8 „ „ „ II., 4 spirochætæ „
„ III., 1 „ 3 „ „ „ III., 1 spirochæta „

Film preparations of the brain, bone marrow, and spleen of one fœtus were examined. Parasites were found only in the preparations from the spleen.

Experiment 1084.—Rat inoculated on April 6th. Three days later, when the blood contained innumerable spirochætæ, it was killed. The fœtuses (seven) were nearly mature. The placentæ were darker in colour than usual but otherwise presented no macroscopical changes. In blood from the uterine vein the spirochætæ were present in very large numbers and in the placental blood they were in such numbers that in the preparation nothing but large bundles of spirochætæ could be seen. In preparations from the umbilical vein one spirochæta was seen in from 5 to 30 fields. The fœtuses showed varying numbers, on an average one to three fields, though in some fields as many as ten spirochætæ could be counted.

Experiment 1178 C.—Rat inoculated on May 26th and killed three days later, when the heart blood showed from 70 to 100 parasites to a field. The fœtuses (seven) were nearly mature. The blood in the uterine vein showed about the same number of parasites as the heart blood.

Placenta.	Umbilical vein.	Fœtus.
I. 60 to 100 per field.	1-5, 1-9, 1-30 fields.	Negative.
II. 30 „ 40 „ „	—	„
III. 10 „ 40 „ „	1-2, 1-4, 1-48 fields.	1 in film.
IV. 3 „ 30 „ „	2-1, 1-6 fields.	1 „ „
V. 30 „ 100 „ „	1-7, 1-78, 1-90 fields.	2 „ „
VI. 30 „ 100 „ „	—	2 „ „
VII. 10 „ 40 „ „	1-57, 1-70, 1-100 fields.	3 „ „

Subinoculations were made from this rat and the fœtuses to ascertain whether the spirochætæ in the fœtal circulation were still infective and as virulent as those in the maternal blood.

Experiment 1182.—Two rats were inoculated from the mother. Both showed many parasites in the peripheral circulation after an incubation period of four hours and passed through the usual course of the infection.[1] Another rat inoculated with three cubic centimetres of citrated heart blood from three of the fœtuses showed two spirochætæ in a preparation of the peripheral blood after an incubation period of six hours. No parasites were seen for the next *two days*, but on the fourth day they were again present and the rat then passed through the ordinary course of infection.

Experiment 1255.—Rat inoculated on July 3rd and killed three days later. The heart blood showed *from* one to two spirochætæ per field. Preparations from the heart blood of ten half-grown fœtuses were examined and parasites were found in very scanty numbers (never more than two to a thick film) in eight of these. In the placental blood there were on an average from one to two spirochætæ per field.

Experiment 1152.—Pregnant guinea-pig. Inoculated on May 13th and became infected after an incubation period of six hours. It died on May 18th and although no spirochætæ were seen in the blood preparations made after death a subinoculated rat showed the parasites on the following day. The two fœtuses were about three-quarters mature. Although preparations of their blood were examined carefully no parasites were found but the inoculation of a rat proved positive after a prolonged incubation period of six days and the infection ran its usual course.

In order to see whether there exists any inborn immunity two young rats, from four to five weeks old, born while the mothers were heavily infected, were inoculated with blood containing spirochætæ. They showed no immunity but became infected and passed through an attack identical with that observed in normal rats of the same age. On a third rat ticks were fed and the parasites appeared in the peripheral circulation after five days, the usual incubation period.

The above experiments lead to the following conclusions: 1. *Spirochæta duttoni* passes through the placenta from the circulation of the mother to that of the fœtus. 2. The majority of the fœtuses carried by an infected mother are themselves infected. 3. The parasites are found in the placenta in approximately the same numbers as in the maternal heart blood, but, on the contrary, occur in very scanty numbers in the fœtal circulation. 4. The spirochætæ in the fœtal circulation show no morphological changes. 5. Infected pregnant rats show no tendency towards abortion, but few of their young, in comparison with those from healthy mothers, reach maturity. 6. The young born of infected mothers possess no marked inborn immunity against infection either by means of direct inoculation or through the bites of ticks.

A CASE OF CARDIAC SYPHILOMA WITH BRADYCARDIA AND OBSTRUCTION OF THE INFERIOR VENA CAVA:

THE AFTER-HISTORY AND A POST-MORTEM RECORD.[1]

BY CHARLES W. CHAPMAN, M.D. DURH., M.R.C.P. LOND.
SENIOR PHYSICIAN TO THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART, SOHO-SQUARE.

IN the session 1897–98 of this society I showed a man, aged 48 years, whose case is the subject of this communication, under the heading "A Case of Bradycardia with Obstruction of the Inferior Vena Cava." The action of the heart was slow and there was a mitral systolic murmur. There were greatly distended and varicose veins over the middle and right side of the abdomen and a similar condition was seen on the outer side of the right leg. This condition, so far as the abdomen was concerned, had existed for at least five years, while the veins of the leg had only recently become dilated. There was a history of an itching sore on the penis 20 years previously. There had been no secondary symptoms and, as the sore had been of little or no inconvenience to the patient, only a short local treatment had been adopted.

During the following session I read a paper on the same case entitled "A Case of Obstruction of the Inferior Vena Cava, probably Syphilitic." In this paper I went fully into the history of the case and detailed the conditions found on examination. A provisional diagnosis was made of obstruction of the inferior vena cava due to pressure from a gumma or to thrombosis from phlebitis. Arguments in favour of the syphilitic origin of the disease were given together with an account of the treatment adopted, the paper concluding with references to recorded cases of syphilitic affections of the circulatory system and to literature bearing on the subject. The account of the case when exhibited and the report of the paper are to be found in Vols. XXXII. and XXXIII. of the Transactions of the Clinical Society.

Up to May 6th, 1905, the man had been a more or less constant attendant at the out-patient room, which means that I had him under observation for eight years, and that he had had dilated abdominal veins for nearly 14 years. There was nothing special to note beyond that he was for the greater part of the time under iodide of sodium, that the pulse-rate ranged between 33 and 44 to the minute, and that there was an entire absence of syncopal attacks. He was never well if the treatment was suspended for more than two or three weeks. He was able to continue his work until his fatal illness.

---

[1] A paper read before the Clinical Society of London.

Early in June, 1905, I was informed that the patient had been admitted into the London Hospital for suppurating appendicitis and that an operation was performed but that he succumbed shortly afterwards to general peritonitis. I at once communicated with the hospital authorities, and it is mainly owing to their courtesy that I am able to give the following account of the post-mortem examination:—

"The abdomen was distended and covered with varicose veins. On opening it there was evidence of appendix abscess and general peritonitis. In the pleuræ there were a few thin adhesions about the right apex and both cavities were dry. At the apex of the right lung there was a patch of obsolete tubercle. The root of this lung with the neighbouring vessels, glands, and mediastinal tissues were firmly matted into a mass of fibro-calcareous material. The rings of the larger bronchi of the right lung were calcified. The pericardium contained an excess of clear fluid. The two surfaces were free. There was great increase of epicardial fat over the right auricle and at the base of the heart. Over the left ventricle and auricle the pericardium was thick and opaque in places. The heart was pyriform in shape, the right side being about the same size as the left; it weighed 15 ounces. The heart muscle was brown and tough with visible strands of fibrous tissue running through it. The left ventricle was dilated but not hypertrophied; the right ventricle and auricle were dilated and contained a small black clot. The cavity of the left auricle was greatly diminished and constricted in its middle to a ring which just admitted the tip of an index finger. The cause of this narrowing was a dense calcareous mass situated beneath the endocardium. This condition of calcification affected the whole circumference of the left auricle, the interauricular septum, the aortic sinus, and first inch of the aorta, being in all places deep. The interventricular septum was thick and muscular.

The valves.—The mitral curtains were thin and pliant, but just above the mitral orifice the left auricle was narrowed by the ring already described. The aortic cusps were thin and pliant. The pulmonic and tricuspid valves were natural. The coronary arteries were narrowed at their orifices but further down were unchanged. The aorta contained many patches of atheroma.

Summary of the condition of the heart.—The calcareous mass produced a condition amounting to mitral stenosis; it also narrowed the left auricle, partially occluded the coronary vessels, and affected the interauricular septum. There was great fibrosis of the myocardium.

The kidneys, beyond a few cortical cysts, presented no gross changes. The liver weighed 56 ounces; it was firm and bile-stained. The left testicle presented a typical diffuse fibrous gummatous condition.

Microscopical examination.—Sections were cut of the heart muscle and left testicle. The condition of the latter confirmed the macroscopic appearance of gumma. The heart muscle showed an advanced general diffuse fibrosis. The walls of the main division of the coronary artery were apparently natural, but there was considerable increase in the adventitia of the smaller arterioles. There was no obliterative proliferation of the intima."

There are two points that may be specially noted. 1. That the initial lesion was so insignificant to the patient that but little treatment was adopted. 2. It is probable that the disease was still in progress when the patient first came under my care in 1897, at which time a lump of the size of half a walnut at the back of the neck was noted and which completely disappeared under mercurial treatment. The prolongation of the patient's life may fairly be attributed to the recognition of the true nature of the case and the vigorous and prolonged treatment.

It is an interesting question whether the bradycardia which had been present for at least eight years was due to myocardial invasion with gummatous deposit and subsequent fibrosis or to an early implication of the orifices of the coronary arteries. The affection of one testicle only is in accordance with the observations of Wilks and Moxon who considered that the unilateral presence of gumma is a ready indication of syphilitic taint.

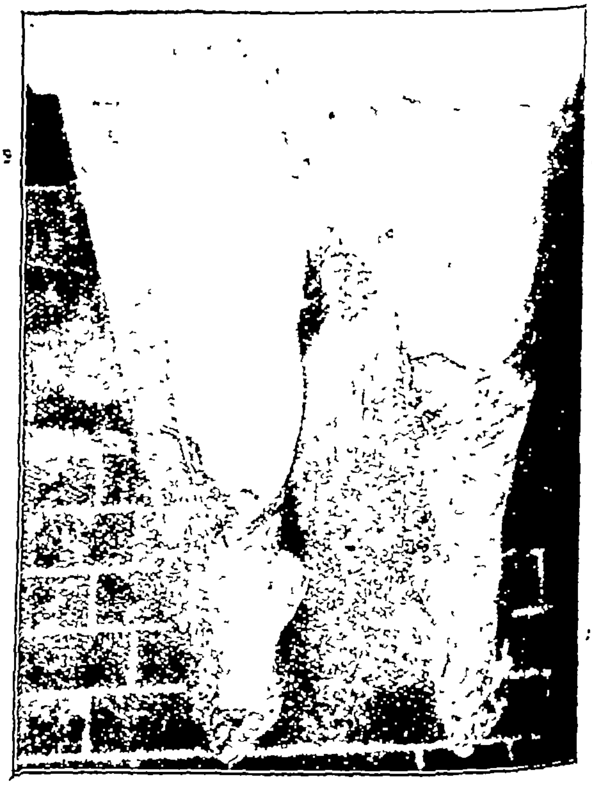
Attention may here be called to a valuable paper on Cardiac Syphiloma by Sir Dyce Duckworth in Vol XXIX. of the Transactions of the Clinical Society. I would particularly refer to the author's closing remarks which I cordially endorse, for they voice the reason and apology, if need be, for bringing this case to your notice for a third time. They are: "The great object is to recognise the nature of the disease as soon as possible and treat the patient by large doses of iodide of potassium. On these lines the best results may be anticipated."

Weymouth-street, W.

GANGRENE OF BOTH FEET AND LEGS DUE TO EMBOLISM AND THROMBOSIS OF THE ABDOMINAL AORTA IN ITS ENTIRE EXTENT, THE RESULT OF MITRAL STENOSIS AND CONSECUTIVE CARDIAC THROMBOSIS.

BY H. W. SYERS, M.A., M.D. CANTAB.,
PHYSICIAN TO THE GREAT NORTHERN CENTRAL HOSPITAL.

THE patient, a married woman, aged 50 years, was admitted on Feb. 3rd, 1906. The history was as follows: On Jan. 20th, being in her usual good health, she first noticed a pain in the right leg; it was not severe and apparently soon passed off. On the morning of Jan. 27th on waking she complained of pain in the toes of both feet; she did not lay up but still felt pain in the toes and feet; in a few days a tingling sensation was experienced affecting the feet and extending up both legs. This latter symptom persisted and gradually became more marked. On admission her only complaint was that of pain in the legs. There was a history of scarlet fever three years previously and of "rheumatism" two years ago. Otherwise the health had always been good. The patient was very well nourished;



The illustration shows the general appearance of the gangrenous lesion.

the complexion was very slightly dusky. Both legs and feet could be freely moved; both were cold and in several localities the skin of the lower extremities was the seat of purplish red patches. There was more or less definite loss of ordinary sensation as high as the knees, but the sensation of heat and cold was retained. The sense of pain was greatly dulled over the left foot and leg, less so on the right side. The skin over the gluteal region was partially anæsthetic and of a purple tint. No pulsation could be felt in either femoral artery and none could be made out in the abdominal aorta, though this was of but little significance on account of the thick layer of fat deposited in the abdominal walls. The heart sounds were entirely free from murmur of any kind and no thrill could be detected on palpation. The apex of the heart could not be clearly defined and the superficial cardiac dulness was very ill-marked. The blood pressure, taken with the Riva-Rocci sphygmomanometer on admission, was 115 millimetres. The urine was of specific gravity 1022; it contained a trace of albumin but no sugar. The temperature on admission was 98° F.

The pain in both legs gradually became more severe and on Feb. 9th the patient could not sleep on account of it, hypodermic injections of morphine being required. The skin over the feet and the legs was now distinctly darker and a few days later the feet had passed into a mummified condition, being also quite black and insensitive. The gangrenous process was now extending somewhat rapidly but more so in the left leg where the skin was more or less discoloured up to the knee. Bullæ had formed in several localities over the gangrenous portions. On Feb. 14th the pulse was noticed to be slightly intermittent. The necrotic process became gradually more marked and on Feb. 26th the feet and a portion of the legs were completely black and powerless; there was complete anæsthesia over the feet and lower third of the legs. The pulse became once more regular and fairly strong; neither murmur nor thrill could be made out on examination of the heart. On account of pain and general restlessness morphine injections were necessary two or three times a day. The temperature continued fairly normal but rose occasionally to 101° at night.

On March 14th there was a purple area about two and a half inches across over the lower third of the right thigh and sensation was markedly impaired over this thigh. Areas of ulceration had now appeared over the left thigh and in the sacral region. Above the left knee and on the inner surface of the left thigh a purplish area was extending upwards and the same thigh was almost in its entire extent red and brawny. The skin over the feet and legs up to the knee on the left side and to the middle third of the right leg, was completely black, the whole being gangrenous. Pain was now much less marked, morphine being seldom required. The pulse now became intermittent and a systolic murmur at the apex was audible. On March 22nd the patient was wandering mentally and the temperature had been somewhat raised (highest 101°) during the few preceding days. She now became very noisy and shortly wildly delirious. The condition of the lower extremities remained unaltered. The pulse became very weak, rapid, and intermittent and death ensued from exhaustion on March 27th.

Necropsy.—At the post-mortem examination it was found that the left auricle was considerably dilated. The left ventricle was somewhat dilated and contained post mortem clot; the left auricle contained semi-decolourised clot, easily removeable, and also a yellowish-grey polypoid mass of about the size of a walnut. This was firmly adherent to the auricular wall at the side of the opening into the appendix; the communication between the auricular cavity and the appendix was completely occluded by this body. The mitral orifice was stenosed, being of the button-hole variety. The cusps were firmly welded together, but there was scarcely any thickening and the edges of the stenosed orifice were not rigid. There was no evidence of recent inflammation. The whole extent of the abdominal aorta just below the origin of the cœliac axis to the point of bifurcation was completely occluded with firm clot which distended the vessel. Both common iliacs were occluded; also the left external and internal iliac and femoral arteries. On the right side the obstruction ended with the termination of the common iliac. The cœliac axis was quite free from clot; all the other branches of the abdominal aorta were blocked at their origin but the lumen was free from this point. The clot filling the abdominal aorta was very firm and was decolourised. Evidence of previous embolic plugging was present in both kidneys in the form of several depressed scars beneath the capsule, the loss of substance extending for about a quarter of an inch into the renal cortex. The lungs were œdematous; all the remaining organs were healthy.

It is well known that of all valvular lesions mitral stenosis is the most liable to be attended with symptoms of embolism. That such symptoms had occurred in the present instance is clear from the condition of the kidneys, which, as will be found on consulting the account of the post-mortem appearances, had been the seat of bygone embolic infarction. There can be no doubt that the heart lesion was directly responsible for the very unusual physical signs observed in this case. Instances of double and simultaneous gangrene of the lower extremities are very far from being of ordinary occurrence and when a case of this kind is met with in all probability the first cause of the condition to suggest itself would be diabetes mellitus. So it was in the present instance. But the urine contained no sugar and all symptoms of diabetes were absent. Then the possibility of extensive and severe atheromatous degeneration of arteries would be entertained; but here, again, there was not the least evidence of this cause of senile gangrene being effective. As far as could be ascertained all the arteries excepting those directly involved were in a healthy state.

The possibility of the lesion being of an embolic nature was not lost sight of and the heart was repeatedly examined. Yet no evidence of cardiac disease could be detected and although, late in the progress of the case, a systolic murmur became audible at the apex, yet there could be little doubt that this was the murmur of failing heart action and due to slight dilatation from this cause.

The entire absence of thrill, of presystolic or other murmur occurring during the diastole, and of reduplicated second sound is certainly remarkable and is a further proof, if such was wanting, that it is impossible in not a few instances to diagnose mitral stenosis, even when the lesion is present in a marked form.

It must surely be excessively rare for such a complication of mitral stenosis as plugging of the abdominal aorta and most of its branches to occur, but there can be no question that the valvular lesion was in the last degree responsible in this case. The presence of the cardiac "polypus" in the left auricle would appear to explain the *modus operandi*. Clearly, either a portion of this coagulum or a similar but much smaller mass must have become free in the blood stream, must have passed through the constricted mitral orifice, and thence must have gained the aorta. That the embolus was of some considerable size seems clear from its obvious extent in the vessel and it would appear to have formed a nucleus for subsequent extensive thrombosis, leading ultimately to the blocking of the abdominal aorta in its whole extent. This case certainly has an important bearing on the somewhat neglected subject of cardiac thrombosis and the relationship of the latter to mitral stenosis.

To Mr. T. W. N. Dunn and Mr. R. Brown, house physicians, I am indebted for the notes from which the history of the case has been abstracted and my best thanks are due to Mr. Alan Hair for his kindness in enabling me to reproduce the general aspect of the lesion from his photograph of the same.

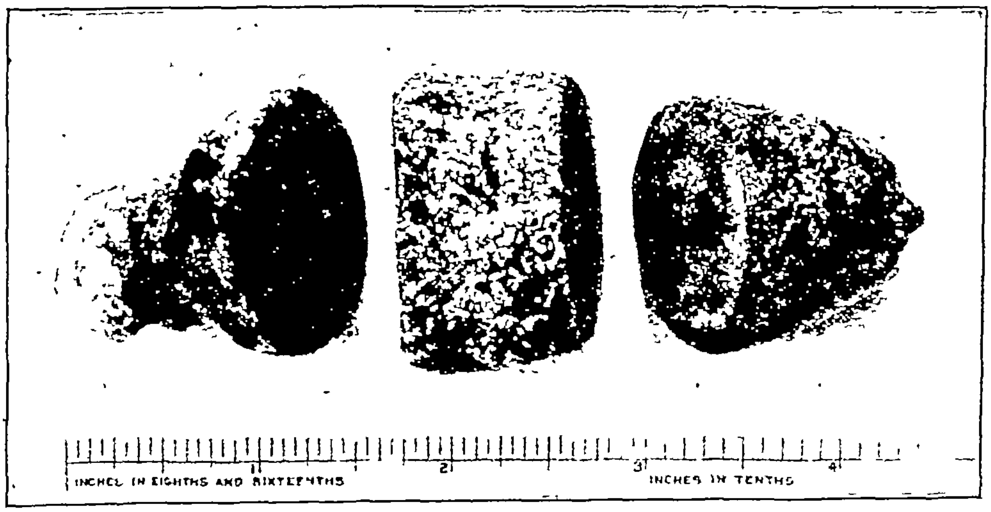
Wimpole-street, W.

A CASE OF GALL-STONES OF LARGE SIZE PASSED BY THE RECTUM.

BY W. E. CARNEGIE DICKSON, M.D., B.SC. EDIN.,
M.R.C.P. EDIN.,
SECOND ASSISTANT TO THE PROFESSOR OF PATHOLOGY IN THE
UNIVERSITY OF EDINBURGH; ASSISTANT PATHOLOGIST
TO THE EDINBURGH ROYAL INFIRMARY, ETC.

THE following case is one of considerable interest, not only on account of the large size of the gall-stones themselves, but also from the fact that they were passed by the patient per rectum, after, in all probability, ulcerating their way through the fundus of the gall-bladder into the transverse colon at or near the hepatic flexure.

The history of the case is briefly as follows. The patient, a female, aged 60 years, was under the care of my father, Dr. George Dickson, to whom I am indebted for the specimens. On July 30th, 1903, while in the country, she was suddenly seized with epigastric pain which became very severe towards morning. A medical man was called in next day and observed that she was slightly jaundiced. The pain subsided during the subsequent day, August 1st, and she was able to go out. During the following night, however, the pain again supervened, accompanied by nausea and vomiting. This condition remained for about a week and then gradually disappeared. The pain, however, returned about a month later, reappearing on Sept. 11th, 1903, and remained present more or less continuously for seven months, a specially severe attack occurring in February, 1904. After this date she felt comparatively well until November, 1905, when she had another short attack of abdominal pain and uneasiness, which lasted more or less till Jan. 14th, 1906, about which time she began to have great difficulty in obtaining passage at stool. On Jan. 19th my father was called to see the patient and on rectal examination found a large, firm, rounded mass, apparently composed of hardened fæces, impacted in the rectum just above the opening of the anal canal and obstructing the outlet. This mass was with some difficulty extracted and its nucleus, after being washed free from the clay-like fæces which surrounded it, proved to be a large gall-stone, 1$\frac{5}{16}$th inches in length, somewhat paraboloid in shape, with a single, large, flat, circular facet, 1$\frac{13}{32}$nd inches in diameter, representing the base of the cone. This stone, which is represented on the right side of the photographs, weighed when dried 14 5 grammes.



Reproduction of photograph (natural size) showing shapes and facets of the gall stones The stone on the right was that passed first. The stones when fitted together made a mass three and a half inches long, forming a complete cast of the interior of the gall bladder. The bulbous projection on the left side probably fitted into the dilated upper end of the cystic duct.

After the evacuation of this stone the patient remained well until April 6th, when she had a severe attack of pain all over the abdomen; and on the 14th a large, firm, tumour-like mass was felt in the left lumbar and iliac regions, its upper margin being on a level with the umbilicus. This mass was moveable and copious enemata were administered in the belief that, as the first gall-stone was faceted, this mass was in all probability due to the presence of one or more gall-stones surrounded by fæces and situated in the descending colon and sigmoid flexure. Mr. F. M. Caird, who was called in for consultation, confirmed this diagnosis and advised the continuance of the treatment by enemata, together with the administration of olive oil by the mouth, there appearing to be no immediate necessity for any operative interference, a course which was amply justified by the fact that during the night of May 10th my father on being called to see the patient, found the two remaining gall stones shown in the photograph impacted in the rectum. These were extracted and, probably owing to the method of treatment employed, were not on this occasion surrounded by the clay-like fæces described as encasing the first stone. These two stones were also faceted and, along with the stone previously passed, fitted together to form a complete cast of the interior of the gall-bladder (see illustration). The stone first passed, and already described, was probably situated at the fundus and was the first to ulcerate into the bowel. The middle stone formed a short cylinder, $\frac{15}{16}$ inch long and 1$\frac{9}{16}$ inches in diameter, and showed a flat facet on each side, one of which fitted the facet of the first stone the other fitting a corresponding surface on the base of the third. The last-mentioned stone somewhat resembled the first in shape, with the exception that it had a curved, bulbous *projection* at one end which evidently fitted into the dilated upper part of the cystic duct. The stones are dark brown in colour, being composed mainly of bile pigment and cholesterin, and on the surface there is a layer of white crystals of cholesterin, giving them somewhat the appearance of having been powdered over with crystals of coarse sugar.

The main interest of the case lies in the fact that gall-stones of such large size were evacuated from the gall-bladder by natural means, and that they had evidently ulcerated their way through the fundus of the gall-bladder into the large intestine after these two organs had become attached to each other by adhesions. They had then passed very slowly down the large intestine, and had become surrounded by a mass of clay-like fæces which led to partial obstruction of the bowels, relieved by the repeated use of large enemata. That they passed down by the cystic and common bile-ducts is very improbable, there having been no severe attack of jaundice, and moreover the stone which formed a cast of the fundus of the gall-bladder was the first to appear in the rectum, and preceded the others by about four months. Ulceration into, and passage by way of, the small intestine is also excluded by the clinical history, and stones of such large size, if they had travelled by the last-named route, would almost certainly have become impacted at the ileo-cæcal valve. A small ischio-rectal abscess formed a few days after the first stone was passed, probably from fissuring of the stretched mucous membrane of the anal canal and infection with organisms. This was opened—about one and a half ounces of pus being evacuated—and rapidly healed up; and the patient is now in good health.

Measurements and Weights of the Stones

—	Diameter.	Length.	Weight (after drying)
	Inches Mm	Inches Mm.	Ounces. Grammes.
First stone passed ..	1$\frac{13}{32}$ = 36	1$\frac{5}{16}$ = 33	0·51 = 14·5
Middle stone	1$\frac{9}{16}$ = 40	$\frac{15}{16}$ = 24	0 67 = 19·0
Last stone	1$\frac{7}{16}$ = 36	1$\frac{3}{8}$ = 35	0 52 = 15·0

Total length when fitted together, 3½ inches (89 millimetres) total weight after drying, 1·71 ounces (48 5 grammes).

Edinburgh.

THE ELECTRICAL RESISTANCE OF THE BLOOD AND URINE AS A TEST OF THE FUNCTIONAL EFFICIENCY OF THE KIDNEY.

BY DAWSON F. D. TURNER, M.D. EDIN., F.R.S. EDIN.,
LECTURER ON BIOLOGICAL PHYSICS, SURGEONS' HALL, EDINBURGH.

IN a communication made to the Royal Society of Edinburgh on Dec. 21st, 1891, I gave an account of the experiments I had made to ascertain and compare the electrical resistances of various kinds of urine both in states of health and of disease. The fluids were held in a U-shaped electrolysis tube containing two disc shaped platinum electrodes arranged so as just to rest upon the surfaces of the fluid, 21 cubic centimetres of which were used for each experiment. The measurements were made by Kohlrausch's method and at a temperature of 65° F.

As a result of the observations, which extended also to artificial urines, it was found that the specific resistance of a normal urine amounts to about 45 ohms and that the resistance is a measure of the salts, chlorides, phosphates, sulphates, &c., present in the urine; the greater the concentration the less the resistance and *vice versâ*. In disease the resistance was found to be increased chiefly in acute croupous pneumonia (due to the diminution in the chlorides), in diabetes mellitus, acute and chronic Bright's disease, and in pernicious anæmia As it is believed that the glomeruli are mainly responsible for the presence of salts in the urine, a high electrical resistance, other things being equal, would indicate an impairment of the function of the glomeruli.

Within the last ten years I have made many attempts to measure the electrical resistance of the blood; various methods (dilution with distilled water, measurement of a column of blood in a capillary tube, &c.), have been employed and subsequently rejected. The principal difficulty depends upon the fact that only very small quantities of blood can generally be obtained at one time. The best results were obtained by placing five cubic millimetres of freshly drawn blood between two cup-shaped electrodes three millimetres in diameter, coated with spongy platinum and fixed at 0·75 millimetres apart. The length of the cylinder of blood between the electrodes is of less importance than its diameter because the cross-sectional area varies with the square of its diameter, and the resistance of a conductor varies directly as its length and inversely as its cross-sectional area. By employing electrodes of fixed diameter and at the same distance apart and the same quantity of blood for each observation and by making the measurement at once before such changes as coagulation or evaporation could occur fairly consistent results were obtained. The average specific resistance of normal blood measured in this way is 93·5 ohms but it may fall to 85 or rise exceptionally to 130. The resistance depends again upon the salt concentration of the blood.

A striking change is to be observed in pernicious anæmia, the resistance in this disease being usually about one-half (50 ohms) that of normal blood. The deduction is that the blood in this disease contains an abnormal amount of salts due either to destructive metabolism or to renal inefficiency or to both. Light is thrown on this question by examining the resistance of the urine; this will be found to be abnormally high, hence we have the striking fact that while the urine contains too few salts the blood contains an abnormal amount. This, then, is a clear case of renal inefficiency. In view of this fact (impairment of the glomerular function of the kidney) the pathology and treatment of pernicious anæmia require reconsideration. These results obtained some years ago and the introduction of cryoscopy have led me to compare this method of determining the renal efficiency with that of cryoscopy and to originate a ratio which I will call "The Hæmo-renal Salt Index"—viz.,

$$\frac{\text{The electrical resistance of the blood.}}{\text{The electrical resistance of the urine.}}$$

In health this would be equal to two or three whole numbers, e.g.,

$$\frac{\text{R. of blood}}{\text{R. of urine}} = \frac{93\cdot5}{45} = 2\cdot08.$$

If this number increases it indicates that the blood contains fewer salts and the urine more and that the functional activity of the kidney is increasing; if, however, the hæmo-renal salt index diminishes it indicates that the functional activity of the kidney is diminishing. Thus in a bad case of pernicious anæmia the salt index is less than one, it is a fraction, but with an improvement of the patient it will at once increase and with his recovery it will return to normal. Here are some illustrations.

CASE 1.—A. B.; healthy.

$$\frac{\text{R. of blood}}{\text{R. of urine}} = \frac{119}{38\cdot25} = 3\cdot1 = \text{hæmo-renal salt index.}$$

CASE 2.—M.; advanced pernicious anæmia; patient under the care of Dr. G. A. Gibson; examined in July, 1906.

$$\frac{\text{R. of blood}}{\text{R. of urine}} = \frac{40\cdot8}{68} = 0\cdot6$$

CASE 3.—A. D.; pernicious anæmia with many relapses; a patient under the care of Dr. A. James; examined in February, 1902.

$$\frac{\text{R. of blood}}{\text{R. of urine}} = \frac{51}{115} = 0\cdot44 = \text{index.}$$

CASE 4.—A. B.; secondary anæmia; patient under the care of Dr. Gibson; examined July, 1906.

$$\frac{\text{R. of blood}}{\text{R. of urine}} = \frac{85}{56\cdot1} = 1\cdot5 = \text{index.}$$

CASE 5.—A. T.; chronic rheumatism; patient under the care of Dr. Gibson. Index 3·3.

CASE 6.—W.; chronic interstitial Bright's disease; patient under the care of Dr. Gibson. Index 2·1.

CASE 7.—H.; recovery from pernicious anæmia; red blood corpuscles, nearly 5,000,000; patient under the care of Dr. Gibson. Index 1·7.

This method is a more sensitive, a more rapid, and a more accurate one than cryoscopy but it does not measure exactly the same thing. Cryoscopy measures the total *molecular* concentration and is independent of the kind of molecule provided they are not dissociated (salts, acids, and bases are exceptions). Electrical resistance depends only upon the salts, acids, and bases, and of these NaCl is by far the most important; it is practically unaffected by the presence of albumin, sugar, and other non-electrolytes.

Urea has a small effect only. The combination of cryoscopy with the determination of the hæmo-renal salt index would give us more precise information as to renal capacity than the use of either method alone; the one method should not be regarded as a substitute for the other but rather as complementary to it, but of the two the electrical method is so much more convenient and rapid that it is likely to come into extended use in the future.

I desire to thank Dr James, Dr. Gibson, and Dr. Woodward for the help they have afforded me in the prosecution of this research.

Edinburgh.

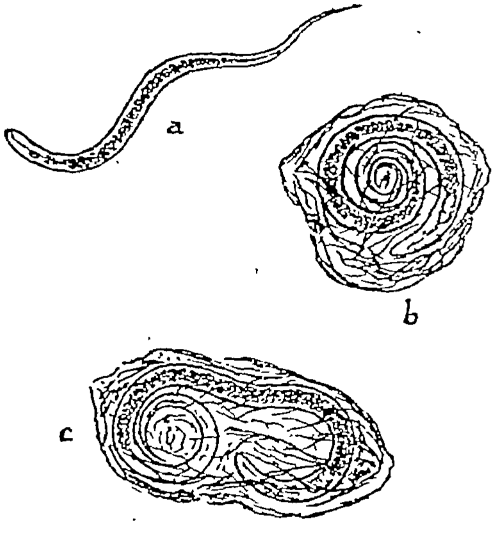
THE POSSIBLE IMPORTANCE OF EARTHWORMS AS A FACTOR IN THE SPREAD OF DISEASE.

BY CHARLES F. FRASER, M.D. BRUX., M.R.C.S. ENG., L.R.C.P. LOND.

IN the alimentary canal of lumbricus or allolobophora a vast number of parasitic organisms exist. Thus in the fore-part of the canal gregarinæ are exceedingly numerous, whilst posteriorly paramecium and other protozoa are seen. Throughout the whole length bacteria swarm, the greater number of the forms seen being bacilli. It is certain that the bacillus of tetanus must be included in the ranks of the latter. These bacilli are extruded in the worm-casts and so contaminate the grass which is subsequently eaten by the horse. It may be that the bacilli are rendered peculiarly virulent by their passage through the worm and we thus have a possible explanation of the frequency of infection amongst grazing horses.

In the posterior part of the gut a parasitic nematode is found which is of peculiar interest on account of its great similarity to trichina spiralis. The nematode exists in a free state and in an encysted form, the former being found nearer the clitellum, the latter in the immediate vicinity of the anus. Thus in a large specimen of allolobophora the last inch of its body will show encysted forms, whilst the intestine higher up exhibits the worm in a free state. It would seem, therefore, that as the worm descends the intestine it becomes encysted preparatory to being extruded in the worm-castings.

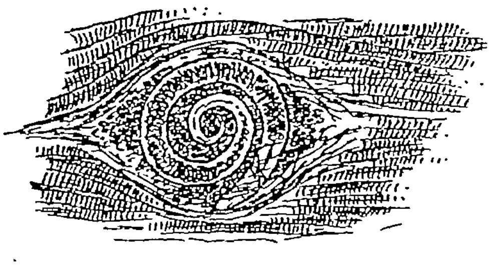
FIG. 1.



Parasitic nematode of worm. *a*, free form; *b* and *c*, encysted forms.

The minute worm is just visible to the eye; the cysts are of the same size as those found in the tissues of persons suffering from trichinosis. They have an irregular, soft, transparent wall, within which the worm may be seen lying, coiled up in a loose, or more often a tight, spiral. The worm never seems to exhibit any movements within its cyst wall. In the free state the worm measures about $\frac{1}{8}$th of an inch in length, is colourless, transparent, and shows an œsophagus, stomach, and intestine, the latter being surrounded by granule-like cells to within a short distance of the anus. The head is somewhat blunted as compared to the anal extremity which is drawn out into a very fine point. The cysts are most commonly found on the walls of the intestine after gently extruding or washing away the earthy contents. They are also present in the intestinal contents and in the worm-casts. It is possible that these may be identical with trichina. Infection of the pig may occur from contamination of the herbage with worm-casts or the pig may eat the lumbricales themselves. Certainly this seems more feasible than the mode of entry usually put forward—viz., that the pig is accidentally infected from eating a rat that has died from trichinosis.

FIG. 2.



Trichina spiralis, appended for the sake of comparison.

It will be of interest to see whether the pig can be similarly infected from these lumbrical parasites.

Cricklewood, N.W.

NOTES ON RHEUMATIC COMPLICATIONS.

BY A. D. PITHIE, L.R.C.P., L.R.C.S. EDIN.,
L.F.P.S. GLASG.,
HONORARY PHYSICIAN TO THE LISLE COURT CONVALESCENT HOME FOR CHILDREN.

THE following case is interesting as having complications of a rheumatic infection without the appearance of the usual symptoms of the disease itself.

The patient was a female, aged seven years. She was sent to Lisle Court Convalescent Home for Children from the Hospital for Sick Children, Great Ormond-street, on June 14th, 1906. On the 15th she was observed to have a clicking sound while speaking. On the 16th she was fidgety at meals, on the 17th unsteadiness in walking was noticed, and on the 18th choreic movements were pronounced, though slight. She was put to bed and kept there. The child remained in this condition until the 21st, when about midnight she became very restless and emotional, with dyspnœa and cyanosis. She was ordered to be isolated and given arsenic and digitalis three times a day, with five grains of trional at bedtime. The temperature was normal and the pulse was 160. She had five hours' sleep at intervals during the night. There was marked cyanosis at 3 A.M. On the 23rd the temperature was normal and the pulse was 158. Trional was given at bedtime and the patient had four and three-quarter hours' sleep at intervals. On the 24th she was still very restless, the pulse was 160, and in the afternoon the temperature ran up to 101° F. Choreic movements were very marked. An ice-bag was applied to the heart, five grains of *bromide of potassium* were given at 4 P.M. and 6 A.M., and trional at bedtime as before. On the 25th she had a much quieter night and the temperature came down to 98°. Up to this time there had been no indications of rheumatism but on this morning she had a perspiration with the characteristic odour of this disease. Seven and a half grains of salicylate of sodium were given every three hours as well as the trional at bedtime, and the ice-bag was continued to the heart. The evening temperature was 100·8°. On the next morning the temperature was 98·6° and the pulse was 140. Salicylate of sodium with an equal quantity of bicarbonate of sodium was given every two hours. The evening temperature was 100·4° and the pulse was 140. Choreic movements were less. Since giving the salicylate of sodium sleep had been better and the patient much quieter. On the 28th the temperature came down to normal and the pulse gradually decreased till on July 5th it was 104, at which it has continued. On the 10th the salicylate was reduced to thrice daily in the same quantity and on the 12th it was discontinued. Trional was discontinued on July 4th. The child is now convalescent.

The child had been sent to the Home for open-air treatment, having been suffering from tuberculous disease, first of the kidney and afterwards of the abdominal glands. When first seen she was found to have the cardiac apex on the level of the fifth rib and two inches to the left of the nipple line. The pulse was so rapid as to be hardly countable. The right auricle was enlarged and there was general hypertrophy of the heart muscle. The temperature was normal for several days till on the tenth day from the time the first symptom of chorea was noticed. Then it suddenly rose and with this rise appeared the sweat with the peculiar rheumatic odour. There were no pains, swelling about the joints, or red splotches anywhere about the child; nor was there anything except the rheumatic smell to indicate the presence of rheumatic infection. The cardiac enlargement was evidently of some standing and on referring to the hospital records there is a note of myocardial trouble but nothing noted as to rheumatism.

Considering the relationship between endocarditis and chorea and the dependence of these on rheumatism it strikes me that treatment of chorea and endocarditis might be carried out on the lines as if they were always due to rheumatic poison. The rapid subsidence of the symptoms and the amenability to treatment by salicylate of sodium and the ice-bag point out a method which might be more universally adopted. The plan of giving bicarbonate of sodium with the salicylate, as mentioned by Dr. F. Langmead, is a safe one even with much more enormous doses than were given in the present instance. In administering larger doses of the salicylate it appears that the danger of acetonuria is obviated by giving at the same time bicarbonate of sodium in an equal or a larger amount. As it is necessary to test for the acetone, and such means are not always at hand to the busy country practitioner, it might be inquired whether the rough-and-ready test for alkalinity would not be to a certain extent a safeguard from acetone poisoning in cases where very large doses of the salicylate are deemed advisable.

Lymington, Hants.

A CASE OF TABES DORSALIS IN WHICH WIDESPREAD CUTANEOUS SENSORY MANIFESTATIONS COMPLETELY DISAPPEARED.

BY FREDERICK W. PRICE, M.B. EDIN., M.R.C.P. LOND.,
MEDICAL REGISTRAR TO WESTMINSTER HOSPITAL.

THERE is a good deal of difference of opinion regarding the question whether the prognosis of the incoördination in tabes dorsalis is influenced by the presence or absence of optic atrophy. Thus, while many writers maintain that with the development of eye symptoms the ataxia often remains stationary, Dr. D. Ferrier in the recent Lumleian lectures expressed the opinion that all that could justifiably be said was that the ataxic and amaurotic forms of tabes are often more or less distinct though not exclusive of each other. Not so much attention has been given to the point as to whether the sensory disturbances are affected by the presence or absence of eye changes. In his lectures Dr. Ferrier pointed out that there is no constant relation between the degree of ataxia and the extent to which cutaneous sensibility is affected. The following case of tabes dorsalis is remarkable, inasmuch as marked sensory disturbances completely disappeared, apparently coincidently with the development of complete optic atrophy.

A man, 34 years of age, by occupation a warehouseman, who had formerly been a soldier, was admitted to the Westminster Hospital under the care of Dr. R. G. Hebb on August 1st, 1905, complaining of weakness and numbness of the legs. There was nothing of note in the family history. The following personal history was obtained from the patient. At the age of 24 years, while in Burma, he had dysentery and malaria; during the same year he contracted syphilis, which was treated for a period of three weeks; there were very few, if any, secondary manifestations. Between two and three years before admission the patient noticed that his sight was failing and this failure of vision gradually increased. About a year ago he found that his gait was becoming unsteady and that he swayed on closing his eyes during the act of washing his face. Soon after this he began to feel numb in the feet, and later successively in the back of the legs, thighs, lower part of the scrotum and fingers. For some months there had been dribbling away of urine on laughing or coughing, and during the last month there had been an aching pain in the lower part of the cervical region after much movement of the head. He had never suffered from lightning pains or from any crises.

On admission the patient was found to be a well-developed man, with a scar, the result of a bullet wound in 1900, in the lower part of the left calf. There was paræsthesia of the feet and tips of the fingers. There was almost complete loss of sensibility to touch, heat and cold, and pain in both legs up to the level of the knees; above that level there was partial anæsthesia up to, and including, the neck and posterior part of the head. Romberg's sign was very evident, the patient almost falling when the feet were put together, even with the eyes open; the gait was typical and very ataxic; there was slight incoördination of the upper extremities. The knee, triceps, and supinator jerks were all absent; the plantar reflex was abolished. There was some loss of control of the bladder sphincter but not of the rectal sphincter. There was slight diminution of visual acuity; the colour sense was normal; the external ocular movements were normal; the pupils were equal, moderately dilated, and reacted both to light and to accommodation. Nothing abnormal was found on examination of the heart, the lungs, or the urine.

Iodide of potassium was ordered internally and a drachm of blue ointment was rubbed into the abdominal wall each evening. Frenkel's exercises were regularly carried out. On August 21st the anæsthesia was found to have somewhat altered, the patient could slightly feel pain over the inner aspects of the knees, and easily recognised touch and pain over both groins; apart from this there was almost complete loss of sensibility as high as the neck and the right half of the face was also less sensitive than normal.

The patient left the hospital on August 25th, his condition having moderately improved. He remained about the same until Christmas, when a steady loss of the power of vision commenced, so that by the middle of April he was totally unable to read, as he said the letters were obscured by lines which crossed one another "like the meshes of a net." He also said that the unsteadiness of gait had steadily increased; the difficulty in regard to his vesical sphincter had, on the other hand, continuously improved, so that there was no longer any trouble with his micturition.

The patient was readmitted on April 30th, 1906. The sensory functions were now found to be absolutely normal; there were no paræsthesia and no impairment of sensibility to touch, heat and cold, or pain; the rate of conduction was normal and there were no pains in any part of the body. Romberg's sign was present; the ataxia of the lower limbs was so great that the patient could scarcely walk without support; he was able to perform fine movements with the upper limbs perfectly well. The plantar reflex and the knee and triceps jerks were all absent. The vesical and rectal sphincters acted normally. With both eyes open the patient was able to distinguish two fingers at a distance of four inches from the eyes; both pupils were of good size, the right being perhaps a little larger than the left; neither was absolutely circular; both reacted to light and accommodation; complete optic atrophy was present. A lumbar puncture was performed and examination of the cerebrospinal fluid showed an extreme leucocytosis, most being small monomorphs (lymphocytes); of large monomorphs a considerable number also; and the presence of a few polymorphs, no doubt due to admixture with blood. Osazon crystals of the thistle-down type were present; the fluid reduced Fehling's solution. The patient was put on the same treatment as before and was discharged on May 24th slightly improved.

It will be observed that the first symptom noticed by the patient was failure of sight. I regret that his discs were not examined when he came under observation on the first occasion, but it is probable that at that time his power of vision was not severely affected, so that optic atrophy, if present, was in all probability slight. Be that as it may, it is evident that in the space of eight months, coincidently with the development of practically complete optic atrophy, the sensory defects not only became arrested but actually disappeared, whilst along with the return of the sensory and bladder functions to the normal there was no improvement but rather a steady deterioration in the coördinating functions. Although Argyll-Robertson phenomenon was not present during the times the patient was under observation, there can be no doubt regarding the diagnosis as the other symptoms were so characteristic.

I am indebted to Dr. Hebb for being allowed to publish this case.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv., Proœmium.

LEWISHAM INFIRMARY.

A CASE OF TETANUS WITH SUDDEN ONSET OF ACUTE SYMPTOMS.

(Under the care of Dr. J. HOBART NIXON.)

A WELL-NOURISHED male child, aged four years, was taken to the infirmary at 8.10 A.M. on July 3rd last suffering from "convulsions." The child was in the position known as opisthotonos. He was bathed in profuse perspiration and the jaws were tightly clenched. His temperature was 99° F. and the pulse at the radial artery could not be felt. Morphine was administered hypodermically and there were a few short intervals in the spasms and the child died at 9.35 A.M. the same day.

The history, obtained from the mother, was as follows. On the evening of June 27th the child whilst playing ran a splinter of wood into his leg. The father withdrew the splinter and bathed the leg with a solution of boric acid. Three days later, as the wound did not heal, medical advice was obtained though the child did not complain of any pain but played about apparently in his usual health. Fomentations were applied and the wound healed. During the afternoon of July 2nd the child complained of "feeling funny in his stomach" but the uneasiness was not sufficient to interfere with his games. The discomfort was more marked in the evening but the child ate several biscuits and sweets before going to bed about 8 P.M. The mother visited the child about midnight when he complained of acute pain in the stomach and in the back of his neck. Soon afterwards convulsions set in and the medical attendant was sent for about 5 A.M. on July 3rd and ordered his removal to the infirmary.

Necropsy.—The post-mortem examination revealed the following conditions. On the outer side of the right leg, situated half-way between the ankle and the knee, was a dry, healed wound, roughly circular in shape and somewhat less than a quarter of an inch in diameter. The presence of any foreign body under the wound could not be felt. But on dissection a narrow track, one and a quarter inches in length, was revealed, at the bottom of which was found a splinter of rough, dirty wood three-quarters of an inch in length. Surrounding the splinter was a small cavity containing pus in which microscopic examination revealed the presence of typical bacilli tetani. Running through the wall of the cavity was a swollen nerve. The stomach was empty and showed no signs of irritation. The meninges and lungs were congested. All other organs were normal.

Remarks by Dr. NIXON.—The points of particular interest about the case are: 1. The superficial healing of the wound, rendering it impossible to tell by palpation that a foreign body was inclosed, though probing would have assisted the diagnosis had the child been taken to a medical man in the first instance. 2. The onset of symptoms was so sudden as to suggest poisoning; the child was playing as usual the previous evening, ate his supper, but died at 9 35 A.M. on the next morning. 3. The position of the nerve to the nidus of infection offered a ready means of transit of the toxin from the lesion of the splinter to the central nervous system.

MELBOURNE HOSPITAL.

A CASE OF A BULLET LODGED IN THE RIGHT HEART; LIFE CONTINUED FOR SIX MONTHS.

(Under the care of Dr. C. S. RYAN and Dr. H. C. MAUDSLEY.)

FOR the notes of the case we are indebted to Dr. Arthur Morris, late resident medical officer to the hospital.

A man, aged 70 years, and well preserved for his years' was admitted to a surgical ward of the Melbourne Hospital on Jan. 19th, 1904. He had been suffering from tabes dorsalis for the previous 16 years and had, apparently on account of the pains, attempted suicide on Jan. 18th by shooting himself in the lower part of the thorax with a revolver. Examination showed a bullet wound, with edges inverted and the skin blackened around it, situated at the level of the junction of the xiphisternum and the body of the sternum. There was very little hæmorrhage from the wound. The abdomen was lax, was not tender in any part, and there had been no vomiting. The patient complained of some pain between the shoulders posteriorly and also beneath the left nipple, while there was tenderness about the site of the wound. The direction taken by the bullet was apparently downwards, backwards, and to the left. On examination with the x rays, using the screen, the bullet was seen to be situated about two inches to the left of the sternum and opposite the sixth left costal cartilage. The patient had no symptoms which called for operative interference and was discharged on Feb. 2nd none the worse, apparently, for his experience.

Nothing further was seen of the patient until Sept. 17th, 1904, when he was admitted to a medical ward in the hospital in an unconscious condition. The history then obtainable was that he had suddenly become unconscious that morning and that the seizure had not been accompanied by any form of convulsion. On examination no reflexes, except the conjunctival, were obtainable. The heart's apex beat was in the sixth interspace, one inch outside the nipple line. The heart sounds were very weak but clear. No bruit could be detected. The second sound at the base was accentuated. The pulse was very small and rapid, with a tendency to be irregular. At this time the previous history was not known and the case was regarded as one of sudden senile heart failure. Appropriate treatment was adopted, but although the patient regained consciousness he died suddenly with marked dyspnœa and cyanosis about four hours after his admission to the hospital.

Necropsy.—There was an old skin scar situated over the lower end of the sternum on a level with the fifth left costal cartilage and corresponding to this on the inner surface of the sternum was a patch of old organised hæmorrhage. The visceral and parietal layers of the pericardium were adherent to each other nearly all over. These adhesions were not very tough, one near the apex being firmer than the rest, while those over the right heart were dark and pigmented. A darkly pigmented cicatrix was present in the anterior wall of the right auricle close to the auriculo-ventricular groove and corresponding to this on the inner surface of the auricle was a small pigmented patch. The bullet must then have pierced the right anterior cusp of the tricuspid valve, leaving a small slit-like opening. On opening the right ventricle the bullet was found lodged and partly buried in the columnæ carneæ of the apex. Part of the bullet projected into the right ventricle and was covered by a thin filmy membrane. The whole of the heart muscle was flabby and the left ventricle was dilated and hypertrophied—a kidney heart in not a very advanced stage of disease. The other organs only showed signs of age, most marked in the kidneys which were tough, pliant, and had confused cortices. The brain was soft and œdematous but no gross lesion was present.

Remarks by Dr. MORRIS.—The above case appears to be of sufficient interest to warrant recording. It is much to be regretted that fuller notes of the condition ante mortem cannot be given. The patient had apparently died from a failure of the right heart, due, it may be, to degenerative muscle changes taking place about the site of the bullet. No microscopic sections were made as the specimen was desired undisturbed.

My thanks are due to those members of the honorary medical staff, under whose care the patient was, for permission to publish these notes.

Medical Societies.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

Ruptured Gastric Ulcer in a Boy.—Operation for Perforating Gastric and Duodenal Ulcer.—Exhibition of Specimens.

A MEETING of this society was held on July 4th, Dr. J. O. AFFLECK, the President, being in the chair.

Dr. G. KEPPIE PATERSON read notes on a case of Ruptured Gastric Ulcer in a boy, aged 12 years. The patient had suffered from pain after eating, indefinite as to position and time after food; sometimes there was no pain after a meal. There was no vomiting or flatulence and the tongue was very slightly furred. The pain continued for 12 days, being only partly relieved by treatment, when after a light dinner in the evening he suddenly felt very severe pain in the abdomen. He was seen an hour afterwards when he was collapsed, with slow pulse, rigid abdomen, normal temperature, and complaining of pain in the abdomen and also in the left shoulder, especially about the left clavicle. After the application of a fomentation and gentle friction all signs of shock disappeared in half an hour; there was no loss of liver dulness. On the next morning he had signs of peritonitis with loss of liver dulness in front. He was operated on by Dr. F. M. Caird 18 hours after the rupture. A ruptured ulcer of the size of a small split pea was found on the anterior wall about two inches from the middle of the lesser curvature. The patient afterwards passed through an attack of double pneumonia so severe that at one time all hope of recovery was abandoned, but the very free *inhalation of oxygen* long continued, with hypodermic injections of strychnine, seemed to be the main element in his recovery. He quite recovered after a very slow convalescence. The cause of the ulcer was obscure. He had never suffered from any gastric trouble and had not taken anything likely to cause injury to the mucous membrane, and there was only slight caries of one tooth as a possible source of oral sepsis. Dr. Paterson included in his paper an abstract of 14 cases of ruptured gastric ulcer in children whose ages ranged from 45 hours and two months up to 13 years. These were all discovered post mortem. Only one other had been discovered on operation, that of Cheyne and Wilbe,[1] in a boy, aged 13 years, who recovered.

Dr. CAIRD then gave a communication on 25 Consecutive Cases of Operation for Perforating Gastric and Duodenal Ulcer. He said that the diagnosis of perforation was generally sufficiently obvious and a history of indigestion could usually be obtained. The classic evidences of gastric ulcer, hæmatemesis and melæna, were generally lacking. The immediate symptom of perforation usually took the form of an agonising pain referred to the umbilical region, causing the patient to "double up"; vomiting generally followed; a misleading period of quiescence often succeeded, the abdominal wall became fixed, and marked tenderness was elicited in the epigastric and suprapubic regions. The anterior liver dulness soon underwent diminution and might even be entirely absent. The leucocyte count varied from 7000 to 25,000. Diagnosis was sometimes doubtful, as it had to be made from appendicitis, acute pancreatitis, rupture of intestinal ulcers, and neoplasms. Operation should be carried out at once and the apparently moribund patient might be roused by intravenous saline transfusion and the use of strychnine. Free incision in the middle line gave most ready access. A rush of escaping gas and fluid verified diagnosis and relieved the embarrassed respiration. A broad retractor introduced at the upper end raised the abdominal wall and allowed of inspection of the stomach. It might be difficult to find the perforation, either from its small size or from its being plugged with lymph or by its inaccessibility. If the lesser sac were distended with fluid then the ulcer must have been on the posterior wall of the stomach. On identification of the perforation the ulcer should be plugged with iodoform gauze and a fresh search made for other ruptures. An incision should invariably be made in the middle line above the symphysis pubis and two glass drainage-tubes placed in the pouch of Douglas. Through one of these the pelvis should be irrigated with warm saline solution, while the ulcer received attention. There was no necessity to excise the ulcer which should be closed with fine silk sutures. The margins might be brought together; then at some little distance from the margins a series of Lembert's sutures must be introduced and a trace of iodoform rubbed in to favour plastic repair. If much perigastritis was present a large infolding of gastric wall might be necessary and lest this might occlude the gastric outlet it was better to perform gastro-jejunostomy. The whole upper part of the abdominal cavity should be thoroughly irrigated. A Keith's tube ought to be left in the pouch of Douglas and usually the site of perforation was drained by means of a Mikulicz tampon and tube. The wound in the abdominal wall was closed and the head of the bed should be raised six inches to favour gravitation of discharge from the highly absorptive upper part of the abdomen. Perforation usually took place on the anterior surface of the stomach and mostly towards the lesser curvature and pylorus. The escape of acid contents from the stomach stimulated the entire peritoneum to secrete an alkaline liquid so as to neutralise the gastric secretion. Recovery was usually uneventful and it was seldom that the stomach contained any very virulent micro organisms. Cultures were made in 11 cases: in seven micro organisms were present; the colon bacillus was frequently present; and in four the results were negative. In considering prognosis, the size and position of the perforation, the date and nature of the last meal, and the amount of escaped material had to be remembered. It was true generally that the *longer* the period which had elapsed since perforation the graver was the outlook. The *age of the patient* and the rate and condition of the pulse afforded valuable information as regarded prognosis. A pulse of 120 was to be feared and if 130 it was to be dreaded. The after-course was full of anxiety. Thirst might be allayed by rectal saline infusion administered every four hours. Morphine might be necessary. If the pulse failed in strength or fulness while the rate increased, intravenous saline transfusion was most beneficial. Vomiting if severe or accompanied by hæmatemesis was best combated by gastric lavage. Pulmonary complications ensued in some cases—e.g., pleurisy and empyema.

Mr. ALEXANDER MILES communicated Observations on Perforated Gastric and Duodenal Ulcer, based on a personal experience of 46 cases operated upon The conclusions to be drawn from a study of these cases might be narrated thus: 1. The liability to perforation appeared to be equally prevalent in both sexes, though females suffered more frequently from gastric ulcer than did males; 20 of the above patients were males and 26 were females. 2 Speaking generally, perforation occurred at an earlier age in females than in males and as a rule the younger the patient the better the prognosis was likely to be. 3. Although perforation occasionally occurred in patients who had not previously complained of any digestive disorder there was in the great majority of cases a history of severe antecedent indigestion and in a considerable number ulceration of the stomach or duodenum had been diagnosed. Hæmatemesis was, however, a rare antecedent symptom. 4. *In a considerable proportion* of the above cases premonitory symptoms of perforation had been present. 5. The actual rupture of the ulcer could not be accounted for by any constant factor. 6. The gastric perforation was situated on the anterior wall in 33 cases and on the posterior wall in three cases only; of these four were at the cardiac end, 14 in the body, and 18 towards the pyloric end. Almost all were situated towards the lesser curvature. The duodenal perforations all occurred in the first part and on the anterior wall. 7. Only in one case was there more than a single perforation. 8. Each perforation varied in size from that of a pin's head to that of a threepenny-piece. It partook of the character of a longitudinal tear in two cases. The size of the perforation bore no relation to the acuteness of onset or severity of symptoms. 9. The suddenness of onset, the overpowering nature of the pain, the marked rigidity of the abdomen, and the severity of the shock all formed the most characteristic clinical symptoms. 10. Emesis was not a common symptom at the commencement and when it occurred it did not increase the gravity of the prognosis. 11. Percussion of the abdomen gave inconstant and untrustworthy information. The disappearance of liver dulness was of no value in diagnosis nor did its persistence negative a diagnosis of perforation. 12. The site of maximum pain and tenderness was a trustworthy guide to the site of perforation and therefore to the line of incision. 13. The apparent improvement which often followed the initial shock was very deceptive and often led to dangerous or even fatal delay in operation. 14. Opium was a dangerous drug to give for the relief of early symptoms. Of 22 cases in which opium was not given 17 recovered and only five died. In 12 cases where opium was given 10 died and only two recovered. 15. Food particles were seldom recognised in the fluid which had escaped into the peritoneal cavity. The size of the perforation or the amount or quality of fluid which escaped from the perforation bore no relationship to the severity of the peritonitis. 16. At the earliest moment the abdomen should be opened by a vertical incision, placed over the site of maximum tenderness. 17 It was seldom advisable to open the stomach to find the perforation. 18. A graft from the omentum should be fixed over the line of sutures used to close the perforation. If so leakage was extremely rare. 19. It was rarely necessary to excise the ulcer and this was not to be recommended. 20. Gastro-enterostomy was an operation seldom to be justified as a precautionary measure against pyloric stenosis or as a means to favour the healing of the ulcer. 21. Pyloroplasty was a simple and efficient alternative in some cases to gastro-enterostomy. 22 The abdomen should usually be washed out and a special opening made above the pubes for drainage. 23. Injections of saline solution were more beneficial. Fluids might be given by the mouth after the lapse of 24 hours. 24. Complications met with had been such as the following: temporary gastric fistula, pneumonia, bronchitis, acute non suppurative parotitis, crural phlebitis, pelvic abscess, and subphrenic abscess. The chief factor in prognosis was the early period when operation had been undertaken. Every hour of delay diminished the patient's chance of recovery. The following was a summary of the results: gastric ulcer, 36 cases, with 18 recoveries and 18 deaths; duodenal ulcer, 10 cases, with 5 recoveries and 5 deaths; total, 46 cases, with 23 recoveries and 23 deaths.

Mr. C W. CATHCART, Mr. J. M. COTTERILL, Mr. H. J. STILES, Mr. R. SCOTT SKIRVING, Dr. JAMES RITCHIE Dr. ALEXANDER JAMES, Mr. R. A. LUNDIE, and the PRESIDENT took part in the discussion which followed.

Dr. CAIRD showed: (1) A Large Vesical Calculus and Prostate removed by operation; and (2) preparations illustrating Perforated Gastric Ulcer.

Dr. ALEXANDER BRUCE exhibited: (1) Two Brains showing large Tumours involving the pituitary body, without acromegaly; (2) one brain from a case of Chronic Chorea; (3) one brain with Thickened Vertebral Arteries involving both spinal accessories; (4) a case of Mitral Stenosis with large spherical vegetation almost occluding the mitral orifice; (5) a Heart with Ulcerative Endocarditis, showing large vegetation on the ventricular side of the mitral valve (aortic cusp); (6) microscopic sections showing Bacilli from Cerebro spinal Fluid and Blood during life and from the vegetation; and (7) photographs of Partial Ophthalmoplegia Externa.

Dr. H. M. CHURCH: Demonstration of Gärtner's Tonometer.

EDINBURGH OBSTETRICAL SOCIETY AND THE GLASGOW OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.—The special annual conjoint meeting of these societies took place on July 11th in Edinburgh, Dr. J. W. Ballantyne, the President of the former society, being in the chair.—Emeritus Professor Sir Alexander Russell Simpson (Edinburgh), Professor A. M. Makejev (Moscow), and Professor L. M. Bossi (Genoa) were elected Honorary Fellows of the Edinburgh Society.—Professor William Stephenson (Aberdeen) opened a discussion on Irregular Manifestations of Puerperal Sepsis. The bacteriologist had now, he said, thrown much light on sepsis and given the facts their due proportion and perspective, as well as advancing knowledge both as to prevention and treatment, but the relation of micro-organisms to the manifestations of morbidity was far from being specifically determined. There were many varieties of organisms, each, no doubt, had a special action, but they could not yet clinically differentiate one from another; the manifestations were similar in all and mixed infection was common. The knowledge of the site and character of the local affection was of great prognostic value. The uniform standard of morbidity, as suggested by the committee of the British Medical Association, was disappointing, as eight days were too short for irregular manifestations of sepsis to show themselves, and to record "all cases in which the temperature reaches 100° F. on any two of the bi-daily readings" would be to include some patients who did not suffer from sepsis; the condition of the breasts alone would occasionally supply such cases. In forming an opinion of a puerperal illness the whole clinical bearings must be taken into account. Any degree of temperature determined upon could not be by itself a standard of morbidity, it was merely a standard of febrility. The temperature of 98·4° was the mean of certain variations; any variations below or which only touched this line were what he (Professor Stephenson) called on the low level and above normal were on the high level. A temperature touching 100° and barely, if ever, touching normal he would consider if continued an indication in most cases of sepsis. But the pulse must be taken into account as well as the temperature and the ratio of pulse and temperature was an important prognostic aid. The condition of a patient was indicated on a clinical chart more by the horizontal character than by the vertical range of the temperature. A high temperature was not dangerous unless continued or accompanied by an undue quickening of the pulse in proportion to the temperature.—Professor Murdoch Cameron (Glasgow) showed the chart of a case where the temperature rose on the fifth day after confinement to 104·8° and ranged high; he saw the case in consultation and injected antisteptococcic serum with marked results, the temperature falling to normal very rapidly. This was repeated on different occasions till it became normal. There was a distinct history of perimetritis. Phlegmasia dolens occurred in both legs, also phlebitis of other veins extending to the arms. The patient was in a dangerous condition but one good point was that she had all through a good digestion. She was now doing well. He distinguished three classes of cases. 1. The sapræmic with foul-smelling lochia, where when the portion of placenta was removed the patient was usually immediately cured. 2. Where the cases were due to absorption of sepsis from the perineum; these usually did well in about three weeks, every day, the condition gradually improving. He considered it of importance to get the kidneys to act freely. 3. Where nothing could be found on examination, the patient had an earthy colour, tremor of voice, furred tongue occasional vomiting alternating with attacks of diarrhœa, with suppression of lochia. These cases were to be dreaded as the signs indicated general sepsis and the patients generally died in the second week.—Dr. A. H. Freeland Barbour (Edinburgh) referred to the possibility of making too much of septicæmia or rather in confusing septicæmia with toxæmia. Many febrile conditions were toxæmic due to other causes than septicæmia. Puerperal rashes were very disquieting as suspicious of a septic condition. He instanced a recent case where a scarlatiniform rash appeared the day after labour with no congestion of the fauces; the temperature was about 99·2° and the pulse was 88. It was found that the patient was liable to a similar rash after cycling or a chill. It was a question whether the muscular activity of labour, which produced a large amount of waste products, might not be the source of a toxæmia. Eclampsia was associated with a raised temperature and yet it was not septic. He instanced another case where there was a rash like measles and noted that in these cases the rash did not come on immediately after the production of the cause but that the toxæmia took time to develop.—Dr. Samuel Sloan (Glasgow) had seen in grave cases the temperature curve with the vertical line frequently coming down to normal. He considered a horizontal line of temperature a little above normal, even just above 99°, if continued as very suspicious of sepsis. He did not put value upon the temperature taken in the axilla, the mouth or rectal temperature being more accurate. He considered the state of the breasts of importance; if the breasts were acting well he had little anxiety about a case even if there were a fairly high temperature and quick pulse.—Dr. S. MacVie (Chirnside) said that in the country it was impossible to obtain regular records of temperature. Some cases with high temperature were not due to sepsis. He had seen a temperature of 103° brought down to normal in 12 hours with a good purge. He believed that the change of diet usually prescribed after labour might make patients more liable to sepsis. He now changed their diet less both before and after labour, allowing them to take more of their ordinary food.—Dr. Charles C. Easterbrook (Ayr District Asylum) said that puerperal mania or insanity was one of the most distressing complications of labour. It was stated that it was less frequent but he did not know of any statistics to prove this. There were two distinct groups: First, that of septic puerperal mania, mostly occurring within a week of labour, with high temperature and pulse and very marked delirium. This required the usual lines of treatment, curetting of the uterus if necessary, &c. He had not found serum injections successful as a rule. These cases were distinctly in the minority in asylums. Secondly, there were those which occurred later in the puerperium where the temperature and pulse showed no distinct evidence of sepsis or where the temperature might be normal. These were just like ordinary cases of insanity and had been produced by exhaustion of the nervous system by the labour, which might be called a natural physiological crisis. There might be a toxæmia due to the absorption of the material, probably an albumose, produced by the involution of the uterus. Toxic rashes were frequently seen in the chronic insane and were mostly due to constipation. In febrile conditions the general level of the temperature was very important; in the chronic insane the temperature had to be considered in relation to their normal, which was usually 97·4°.—Dr. Claude B. Ker (Edinburgh Fever Hospital) stated that severe forms of sepsis from whatever cause, especially if going to be fatal, often had rashes and usually scarlatiniform. Scarlet fever was always true to its signs and true scarlet fever does not occur in sepsis. Many conditions would cause rashes. Constipation was a very great factor but strangely these did not occur during its persistence but after an enema or salts for its relief. He had noticed this in the typhoid cases where routine irrigations of the bowel are carried out and with all sorts of curious rashes as a result. He considered it due to the walls of the colon being cleared and the contents being well diluted and absorption thus promoted. A surgical operation might be the cause of a scarlet rash and a very small wound of the perineum might be a source. The general level was the main condition in estimating the value of a temperature. He did not feel secure from a relapse in a case until there was a level subnormal temperature. The cases of puerperal sepsis sent to the fever hospital usually had no symptoms but the temperature and were mostly fatal.—Professor Dickinson (New York) did not consider that they got much practical assistance from the bacteriologist—enough to throw out the rarer and more dubious forms of sepsis. But he was disappointed that there was so much sepsis in practice. As teachers they must impress upon their students the fact that obstetrics was not medicine but surgery and that it must be attended with everything surgically clean. There were fashions in the treatment of these cases; the injection of serum was thought at one time to work wonders and the results showed that the fatality was 40 per cent., but the fatality of those treated without serum was also about 40 per cent. Then the leucocyte count had also given out in its value. The polynuclear cells if above 80 might yet give valuable indications of the state of sepsis. They had reduced the death-rate in New York by organising an outdoor midwifery department attended by students who must keep accurate records of their cases. The great points in prevention were clean hands and a clean vulva. He instanced a case where there was a persistent moderate rise of temperature and where every ten days there was a very severe uterine hæmorrhage, almost causing death; after the third hæmorrhage the uterus was removed and was found to contain a small infecting ulcer close to one of the uterine arteries. He believed that a great many of these septic cases were due to phlebitis. At one time it was common with them to open the cul-de-sac in all septic cases and in from 30 to 40 per cent. serum or pus was found and then they put in a drain. Now that treatment had fallen into disuse and instead they incised the broad ligaments and often found and cleared out small phlebitic clots.—Dr. E. H. L. Oliphant (President of the Glasgow Society) thought that many cases of high temperature arose from toxæmia and not from sepsis. In the Glasgow Maternity Hospital he had found the temperature rise to a very high degree due to emotional causes; in these cases it rose suddenly, did not maintain a high level, and fell as suddenly. They had experienced a slight scarlet fever epidemic in the Maternity Hospital, but the rash and signs were quite typical in these patients. He instanced a patient who had a rigor on the fourth day accompanied with pain below the ribs on the right side. He took a swab of the contents of the uterus and found a pure culture of pneumococci. Two days later the patient showed signs of pneumonia.—Dr. J. C. G. MacNab (Dysart) said that germs flourished in patients of lowered vitality and that the general condition of the constitution was of great importance. The determining cause of rashes was difficult to find: he had two operations—one a herniotomy where no antiseptic lotion was used, only sterilised water; and another, a case of operation for septic mastoiditis, and yet both had similar scarlatinal rashes.—Professor R. Jardine (Glasgow) had seen a great many cases of puerperal rashes and also rashes after operations. Sometimes it was very difficult to distinguish them from true fever when they were accompanied with rise of temperature. He considered the aspect of the throat the main point in the differential diagnosis. As causes of rise of temperature other than sepsis, he mentioned excitement, as he had often seen it occurring in patients on the night before leaving the Maternity Hospital, due to their finding out some disturbing element at home. He had met a number of cases of rise of temperature due to the condition of the bowels. At one time he watched carefully day by day the progress of the involution of the uterus. He found some cases where there was very rapid decrease of the uterus, even in 24 hours falling below the pelvis, and in all these cases there was a rise of temperature, even up to 105° F., due to the absorption from this source. He had seen irregular manifestations due in several cases to abscesses, such as of the kidney and between the diaphragm and stomach, from a ruptured ulcer.—Dr. J. W. Ballantyne alluded to the conference in London on puerperal morbidity. They had suggested a uniform system of nomenclature, and for morbidity agreed to exclude the first day and any manifestation beginning after the eighth day, and provisionally that three bi-daily readings above 100° F. with a pulse above 100 indicated puerperal morbidity. At the Edinburgh Royal Maternity and Simpson Memorial Hospital out of 100 cases four fulfilled these conditions and these all recovered but others with rise of temperature died. He instanced a case of puerperal insanity in which the patient had to be removed to the asylum and died six weeks after labour, when post mortem a small abscess of the uterus was found.—Professor Stephenson replied.

BRITISH GYNÆCOLOGICAL SOCIETY.—A meeting of this society was held on July 12th, Mr. F. B. Jessett, the President, being in the chair.—Dr. S. Jervois Aarons showed a Modified Hollow Ring Pessary filled with a mixture of gelatine and glycerine used in retroflexion with prolapsed ovaries.—Dr. R. C. B. Maunsell showed the following specimens: 1. Uterus and Adnexa removed by Wertheim's operation for malignant disease of the cervix. The glands were removed up to the kidneys and although enlarged yet no evidence of malignant disease was found. The ureters were easily found by tilting forward the ovaries when they readily showed through the peritoneum. The patient had urinary leakage on the tenth day which healed up in a few weeks after the bladder was washed out regularly. 2. Specimen of Carcinoma of the Right Ovary from a single patient, aged 25 years, who complained of a swelling in the abdomen for five months. On opening the abdomen some ascitic fluid was found and there were adhesions between the tumour and surrounding structures and also between the liver and anterior wall of the abdomen. The left ovary contained a small cyst which was not malignant. The patient had increased in weight and so far there was no evidence of metastasis or recurrence. 3. Myoma of the Cervix from a patient, aged 47 years, who had metrorrhagia for two years. The tumour bled profusely when touched, so that vaginal plugging was necessary. On drawing the tumour down it was found to be attached by a narrow pedicle which was snipped through with scissors. The patient recovered satisfactorily. 4. A Tubo-ovarian Abscess of one side and Salpingitis of the other tube removed from a multipara, aged 24 years, 15 months previously. The patient continued well for some months and then complained of severe pain and vaginal discharge. The uterus was removed and was found to be in a condition of suppuration. The patient made a good recovery. 5. Two large Tubo-ovarian Abscesses of gonorrhœal origin removed from a patient, aged 23 years, who had no children and had been married about a year. She complained of vaginal discharge and pelvic pain. Before operation she had two attacks of sudden severe pain and when seen was collapsed. On opening the abdomen pus welled up from the peritoneum and both tubal abscesses were found ruptured. Two incisions were made, one above and the other below the umbilicus; the abdominal cavity was washed out and drained with gauze. The patient made an uninterrupted recovery. 6. Two Tubo-ovarian Abscesses which ruptured before operation. The same line of treatment was adopted as in the former case but the patient died a few days afterwards.—Dr. H. Macnaughton-Jones showed a specimen of Hydatidiform Mole removed from a patient, aged 20 years, who had been married 18 months and had one stillborn child at term. She considered herself to be four months pregnant but had had a hæmorrhagic discharge for some time. The uterus was emptied and the specimen showed degenerated decidual tissue and chorionic villi with hyperplasia of Langhans's layer and syncytial buds. As a precautionary measure the uterus was curetted two months afterwards.—Dr. James Oliver read a paper entitled "A Study of Hydatidiform Mole with the Records of Three Typical Cases." After mentioning the theories of menstruation and expressing himself in favour of the view that there was no destruction of tissue, he briefly described the anatomical relationship between the allantois and chorion. The pathogenesis dated from the embryonic period between the third and sixth weeks. The interaction of allantois and chorion was at first harmonious. This interaction might be disturbed by the vigorous local growth associated with the formation of the placenta and might induce a perversion of the function of the allantois which might prejudicially influence the vessels and more or less obliterate them so that a mole might result. The functionally deranged placental and even non-placental villi might excite such reaction in the uterine wall that a more or less intimate union might be established between embryonic and maternal tissues so that the morbid process connected with this union might be injurious not only during gestation but also after abortion. Hydatidiform mole might be found at any time during reproductive life. The symptoms were then detailed. The association of amenorrhœa with the presence of a mole raised an interesting point, as in cases of intra-uterine death it could not be assumed that the suspension of menstruation could be solely due to the presence of a perished ovum in the uterus. The derangement was probably due to some disturbance in the metabolism of the uterus, for the abortive or aberrant product of conception attracted to itself and absorbed nutriment which was elaborated and practically secreted by the endometrium. The demand made thus upon the uterus was very different from that made by an ordinary neoplasm and induced such an alteration in its physico-chemical state generally that not only was menstruation held in abeyance but the irritability was so impaired that it might tolerate for an indefinite time the presence of a vesicular mole in its cavity. A uterus of a smaller size than ought to be considering the suspected duration of pregnancy was an important phenomenon. Three cases of molar pregnancy were then detailed and a discussion followed.

Reviews and Notices of Books.

Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India: Mediterranean Fever in India; Isolation of the Micrococcus Melitensis. By Captain George Lamb, I.M.S., and Assistant Surgeon M. Kesara Pai, M.B., C.M. Calcutta: Office of the Superintendent of Government Printing. 1906. No. 22, New Series. Price 10 annas, or 1*s.*

Some doubt has recently been cast on the belief that the fever with which the name "Malta" is associated has a wide geographical distribution. Whatever may be the truth of this doubt as regards the appearance of this disease in many parts of Italy, Greece, Turkey, Palestine, Africa, Southern China, Fiji, and localities in the Western Hemisphere, there can, we think, be no hesitation in asserting that it occurs in India. Of the truth of this the facts related in the above memoir afford ample proof. Thus Wright and Smith have tabulated ten cases invalided from India. Birt and Lamb, again, observed ten other examples at the Royal Victoria Hospital, Netley, in patients who had been invalided for enteric fever, malaria, and rheumatism. In 1900 one of the authors of the memoir, working in Bombay, studied five cases contracted in that city; four cases a short time afterwards were diagnosed in Simla both by the clear clinical symptoms and in two of the cases by the sera giving positive reaction with the micrococcus Melitensis. In 1901 Greig reported three cases in the Swat Valley. The authors hold that the serum agglutination method for the diagnosis of Mediterranean fever when properly and rigidly controlled is a most delicate bacteriological test and that it ought to take its place as an important addition to the ordinary clinical methods for the diagnosis of the disease. This opinion is evidently shared by the Commission that was appointed for the investigation of Mediterranean fever under the supervision of an advisory committee of the Royal Society. The work of the two authors of the report under review amply confirms this view.

The diagnosis of the fever was arrived at by reason of the sedimentation test and in a considerable number of the cases it was proved to be correct by the isolation from the spleen during life of a coccus bacteriologically indistinguishable from the micrococcus Melitensis. The technique employed by the authors and the precautions taken to control their observations are detailed and were briefly as follows. All agglutination experiments were made macroscopically in the capillary tube of Wright, by means of which also the serum dilutions were effected. Equal quantities of the various dilutions of the serum made with normal salt solution and of a sterile emulsion of the micrococcus were employed in all instances. The preparations were allowed to stand at laboratory temperature (about 18° C.) for 24 hours when the results were recorded. The emulsions were all made in exactly the same way—namely, a uniform growth on agar of from four to seven days was emulsified with normal sterile salt solution, about 2·5 cubic centimetres of the latter being used for each agar culture; the bacteria were then killed by heating at 60° C. for 15 minutes and finally 0·5 per cent. carbolic acid was added. *At the same time control experi*ments with the blood of healthy individuals and of patients suffering from other diseases were made almost daily—viz., with the bloods of 51 healthy individuals, all natives of India, and with all bloods sent to the Pasteur Institute of India for serum diagnosis of typhoid fever, about 150 cases. Thus the two series of controls amounted to over 200 in number and show that the bacteriological test is a delicate, easy, and absolutely trustworthy method of diagnosis.

The cases of Mediterranean fever coming under the notice of the authors fell into two groups—viz., (*a*) those in which the micrococcus Melitensis was isolated from the spleen during life and (*b*) those in which the diagnosis rested solely on the clinical history and the serum agglutination reaction. The bulk of the memoir is taken up with a recital of the cases which go to prove the fact that Malta fever does occur in India. It concludes with a highly interesting account of the disease as occurring in the 15th Sikhs at Ferozepore, who were evidently infected from a pre-existing source in the same station. The whole report demonstrates that Malta fever is not peculiar to Malta and it will well repay a perusal.

Infant Mortality: a Social Problem. By George Newman, M.D. Edin., D.P.H Cantab., F.R.S. Edin. London: Methuen and Co. 1906. Pp. 356. Price 7*s.* 6*d.*

If proof were required of the truth of the familiar saying that "the people perish for lack of knowledge" this would be supplied by a study of the present work on Infant Mortality, for an advance copy of which we are indebted to Dr. George Newman, the medical officer of health of the metropolitan borough of Finsbury. Very opportune is the appearance of this volume at the present juncture, when the public conscience has at length been aroused by recent revelations concerning the terrible sacrifice of infant life which continues year after year in this country. And its publication a few days before the opening by the London County Council of the National Conference on Infant Mortality was doubtless turned to good account by the President of the Local Government Board who, in his interesting inaugural address at the Caxton Hall,[1] spoke in highly appreciative terms of Dr. Newman's work. In the interval which has elapsed since receiving it we have taken the opportunity to peruse carefully the book and we may say at once that it bears evidence of careful and thorough composition by one who is eminently qualified for the task. As far as we know this is the only modern text book of any pretensions to scientific accuracy that is available to the

---

[1] A notice of this conference appeared in The Lancet of June 16th, p. 1710.

English reader, and we predict for it a wide circulation, not by any means limited to students or practitioners of medicine.

The term "infant mortality" is used by the author, as, indeed, by most of his contemporaries, to express the ratio of deaths under one year of age to registered births. And so long as stillbirths continue unregistrable in England this method is at least as trustworthy as any other at present available.

Dr. Newman emphasises the Registrar-General's announcement that almost exactly one-quarter of the total deaths occurring every year are those of infants who have not attained the first anniversary of their birth. The national registers record nearly 1,000,000 births and more than half that number of deaths annually, and out of those 500,000 deaths at least 120,000 are dead infants—"a vast army of small human beings that lived but a handful of days." But this is not all, for proportionally to population there were last year four births fewer in every 1000 persons living than there had been in the same number of persons in 1851. If the birth rate were to-day the same as it was in the middle of last century there would be every year more than 60,000 additional infants born. Whilst commenting with satisfaction on the recent substantial decline in the English death-rate *at all ages* Dr. Newman rightly insists on the importance of discriminating the ages at which this improvement has taken place. "In England and Wales," he says, "there has been no change in the infant death-rate, the deaths of infants still continue at the old high rate—one in six dying before it is twelve months of age." Nor is England alone in this respect. In other civilised nations also, with few exceptions, the birth-rate is declining and the same is true of the general death-rate. But infant mortality, as a rule, is stationary or even increasing. The Registrar-General is quoted as responsible for the statement that in the Australasian Commonwealth, as well as in New Zealand, Ireland, Norway, Sweden, the Netherlands, Switzerland, and Denmark, it shows signs of decreasing, the death-rate of infants falling to a comparatively low figure in several of the countries last mentioned. But the foregoing are exceptions. In foreign countries, as a rule, infant mortality is higher than in Great Britain and in some of them—e.g., Austria and Chili—it reaches extremely high figures. But the author goes further in his analysis of infant mortality and shows that the chief incidence of death among infants is upon the earliest months of life. Of the deaths under one year in this country nearly half take place within the first three months, against 21 per cent. in the second three months and 30 per cent. in the last six months of the first year. Going still further, we note that in the first month of life a higher proportion of infants die than in any other month of the first year. Dr. Farr has shown that a like excess of incidence was noticeable in 1864. Thus, 57 per cent. of the total infant deaths occurred in the first month, after which the rate decreased almost steadily until the twelfth month, when it was less than 10 per cent. of the whole.

As regards the topographical distribution of infant mortality, we learn that it is highest in the Northern and North-Midland districts and lowest in the area south of a line drawn from the Wash to the mouth of the Severn. On reference to the map of England it appears that the imaginary line which divides the high mortality districts from the low is also the line which divides the agricultural from the industrial, particularly the mining and textile, portion of the community. Some counties are characterised by a uniformly high, and others by a uniformly low, infant mortality. Among the former are Northumberland, Durham, York, Lancaster, Chester, Stafford, Nottingham, Leicester, and Warwick. Among the latter are Westmorland, Wiltshire, and Dorset. This state of things is not peculiar to any one year or to any recent group of years, the counties that in 1891–1900 showed either a high or a low death-rate having been similarly circumstanced in the preceding decade. But in order to exhibit the extremes of mortality it is necessary to compare areas smaller than counties, to contrast the rates of exclusively urban areas with those of areas that are mainly rural. This Dr. Newman has done and he has shown that the rate in certain industrial English towns is more than double the rate prevailing in definitely rural districts. Whatever may be the effect of density as such on the health of the people, it is certain that the excessive fatality prevailing in many urban districts is, as Dr. Newman expresses it, "an effect of the towns," the older and denser parts of each great town being the most destructive to infant life and the outer zone the least destructive. The distribution of infant mortality in Great Britain follows mainly in the wake of "urbanisation" combined with the industrial and social conditions accompanying it. In its most acute form it becomes a problem of town life. Rural life as found in agricultural counties appears to be favourable to infancy, probably owing to concomitant social conditions and domestic habits. The diseases that are most destructive to infant life are: (1) immaturity, which causes 30 per cent. of the total deaths at this age; (2) lung diseases, 17 per cent.; and (3) diarrhœal diseases, 14 per cent. Atrophy and congenital defects are grouped together with premature birth to form the first of these classes, as having an ante-natal origin. These children are born in such poor physical condition that they are unfit to live and find a few hours or days of extra-uterine life too much for them. They are not so much diseased as merely unfit, and are either not ready or not equipped for separate existence. In a table copied from the Registrar-General's last report the incidence of these and other groups of disease is shown upon urban and rural districts respectively on the average of the last five years.

It is noteworthy that whilst lung diseases and diarrhœal diseases are vastly more fatal in the towns than in the country, "wasting diseases," as they are called by the Registrar-General (Group I. of Dr. Newman), are almost as destructive in the country districts as they are in the towns of England. We have not space to follow Dr. Newman in tracing to their causes the various forms of disease that afflict infant life but it may be stated generally that diarrhœal diseases are intimately related to artificial feeding of infants which nowadays seems to be supplanting breast-feeding in practically all sections of society and that most of the other post-natal causes of death must be considered in relation to the employment of the mothers, the mortality of infants being high or low according as they are left or are not left to the guardianship of "caretakers."

An extremely interesting section of the book is that which treats of the occupation of females as tending to injure young women and prospective mothers and through them their offspring. It is largely based on the evidence given by the lady inspectors of factories before the recent Committee on Physical Deterioration. Dr. Newman summarises this section of his book thus—the operations of female factory labour are three-fold: "First, there are the ordinary injuries and diseases to which women and girls in factories are liable; secondly, there is the strain and stress of long hours and hard work to the pregnant woman; and, thirdly, there is the absence from home of the mother of the infant. It cannot be doubted that these are the factors in the relation between factory occupation of women and a high infant mortality."

Dr. Newman suitably acknowledges his indebtedness for the materials of his book to Dr. Tatham and to Sir Shirley F. Murphy as well as to several other well-known sanitarians whose writings he has drawn upon extensively. In conclusion, we cordially recommend the work to the attention of medical officers of health and of all others who are interested in this important question.

The Morphology of Normal and Pathological Blood. By GEORGE A. BUCKMASTER, D.M. Oxon. With five plates, some coloured, and 14 illustrations in the text. London: John Murray. 1906. Pp. 244. Price 10s. 6d. net.

A COMPLETE knowledge of the literature on the blood is practically beyond the reach of anyone. Although the various excellent works on this subject which exist in English have not been consulted the author appends 14 pages of references to authorities which have actually been consulted. The work consists of eight lectures delivered in the University of London. Regard has been had to the close relationship of physiology and pathology to medicine, so that in this volume the physiologist, the pathologist, and the medical practitioner will find the latest and the best that recent scientific investigation has to record on a subject which daily becomes of greater and more extensive import and significance.

The first two lectures deal with the red corpuscles generally and with many specific points connected with them, such as their specific oxygen capacity, their behaviour to stains, polychromatophilia, hæmoglobin content and its condition in the corpuscles, and the polycythæmia of high altitudes. The red corpuscle possesses no single feature that can with certainty be relied upon as evidence of its life; it shows no sign of metabolic activity and exhibits a function which is purely chemical and physical in character—that of an oxygen carrier. Indeed, our knowledge of the origin of the red disc and its duration of life is still limited; in fact, our knowledge is so limited that "we are entirely ignorant either as to the place or manner of formation of hæmoglobin." The author regards polychromatic staining as a sign of degeneration. In regard to polycythæmia the number of corpuscles may vary greatly in health and the author does not attach much importance to a simple count of red discs. It appears that both the number of corpuscles and the percentage of hæmoglobin augment during residence at high levels. Very interesting experiments are given on this subject in the second lecture.

In dealing with hæmolysis within and outside the organism the author assumes the existence in the red discs of a surface layer or envelope of varying permeability. Regeneration of red corpuscles and hæmoglobin may take place after excision of the spleen. As to the action of hæmolysins, which can be artificially produced in sera, the only test is given by their behaviour towards certain red corpuscles. It is a definite toxic substance for a specific body, the red corpuscle. They are all destroyed by a temperature at 55° C. maintained for half an hour, which distinguishes them from other toxins and certain ferments.

The fourth lecture is devoted to the white corpuscles of the blood. This lecture deals fully with the subject both historically and from a practical point of view. The leukæmic lymphocyte is probably not necessarily connected with purely lymphoid tissue. Of the abnormal cells which may be found in blood the majority appear to have migrated from the bone marrow. For the examination of fresh marrow the author strongly commends the elder-pith method introduced by Arnold of Heidelberg.

The fifth lecture deals with leucocytosis, leucopenia, and leucolysis, a chapter of special interest and most suggestively treated. The next lecture is devoted entirely to blood plates. A full account is given of Deetjen's method which enables the observer to see an enormous number of these bodies, which appear "like a miniature starry heaven" on the thin sheet of solid agar. That they disappear rapidly and show blood is incorrect. The author holds that platelets are produced both inside and outside the body by damage to the blood plasma (p. 121). Indeed, he believes that the platelets are artefacts or pathological bodies which, according to their orgin, fall into four groups: (1) those containing hæmoglobin; (2) those destitute of hæmoglobin, (3) those with an inner body; and (4) those without an inner body

The seventh lecture is of more purely chemical and forensic interest, being concerned as it is with the guaiacum, hæmin, and biological tests for blood. It deals fully with the subject of "precipitins" The eighth lecture is a comprehensive one and is of great interest to medical men, as it discusses the morphology of pathological blood.

A most valuable appendix (pp. 181–218) dealing with selected clinical methods for investigation of the blood and fluids from serous cavities will prove most useful, as much that is obsolete in methods has been omitted while those that have proved of value are fully set forth.

We strongly recommend this work to the consideration of the physiologist, the pathologist, and the practitioner of medicine. It gives the latest and most trustworthy results, résumé, criticisms, and methods in regard to that fluid which we know from Mephistopheles "is juice of quite peculiar kind."

The Report of the Departmental Committee appointed by the Board of Agriculture to inquire into the Ætiology, Pathology, and Morbid Anatomy of Louping Ill and Braxy. Printed for the Government by Darling and Son, Bacon-street, E. In three Parts. 1906.

THIS report, consisting of three separate blue-books, one of which contains no less than 342 pages, is the result of an investigation carried out by a committee consisting of Professor D. Hamilton, Dr. McI. McCall, Mr. Wheler, Mr. Craig, Mr. Young, and Mr. A. Berry, all of whom are well known in the medical, veterinary, and zoological worlds. The investigation was commenced in the spring of 1902 and was carried out until the end of last year. The species of animals affected and the sources of contagion, particularly with reference to the agency of the tick and the different methods by which animals could be inoculated, are related in full detail. Maps have been made showing the distribution of the two diseases in various parts of Scotland, and an organism has been detected to which the ailment known as louping ill can be attributed. The reports are full of interesting bacteriological data and the summaries of the investigation of the two diseases are as follows.

"Braxy and louping ill form two of a group of specific bacterial diseases, the primary habitat of the bacteria which are the cause being in each case the alimentary canal. The germs of this group of diseases are picked up by the animal when feeding and the fatal effect may be prevented by drenching with the culture of the respective bacilli during the period of resistance. At some seasons of the year the blood of the sheep destroys the bacteria and at such times the animal is proof against them; at other times the blood is unable to resist the invasion of the bacteria and death ensues.

A very remarkable discovery was made with regard to the question of susceptibility and immunity. It was found that if the blood of a healthy sheep was placed in a test tube, a culture of the louping ill bacilli added to it, and the mixture inoculated into the body, very opposite results were obtained at different seasons of the year. If this was done in the spring, during the louping ill season, the organism as a rule multiplied freely in the blood, whilst at other times of the year the blood destroyed the bacilli, and a period was eventually reached in July and August when this bactericidal action of the blood became complete. During certain months of the year the louping ill bacilli may apparently reside and multiply in the alimentary canal without occasioning any injury to the sheep; in fact, e walls of the stomach and intestine form a complete rrier to their passage into the peritoneal cavity or into e tissues. This seems to be due to the blood having an fluence inimical to their growth at these particular times. hen the contagious period, viz., spring time, approaches, ving to the blood failing in its power to destroy the bacillus, e protective influence is lost and the organism, if now cked up by the sheep for the first time, is able to pass rough the wall of the intestine with facility. Thus sheep, hich when grazing pick up the organism during the season hen they are not susceptible, usually allow of its passage ong the intestine without detriment and are rendered mmune. Few, if any, become infected a second time.

The most important result of the investigation, when condered from the view of the owner of the sheep and of the nimals themselves, is that certain experiments were done to ndeavour to find out a preventive treatment and the results ppear certainly to have been, so far as they went, satisactory. The drench which proved most satisfactory was repared by incubating the specific bacteria on geloze-beefea, a small quantity of which, mixed with water, was dministered to each sheep by the mouth, a second dose eing given from a week to a fortnight later.

According to the report "the results have proved eminently atisfactory." For example, in the case of louping ill, in he first series of experiments ten sheep were treated in June, 903, and none of them died from the disease. In the second eries 175 were treated and two only died from louping ill, hilst in the third series of experiments 1340 were treated nd only one died, that being considered to be a doubtful ase. In regard to braxy 34 sheep were treated in the first ries of experiments and none of them died from this isease, whilst in the second series 1534 were subjected to e drenching experiments and only nine (of which at least ree were doubtful) succumbed. The report has added aluable knowledge to two of the least known of diseases of eep and, as stated, distinctly demonstrates what necessity ere is for a more extended and trustworthy knowledge of eir nature and causes. We may conclude with a quotaion from the introduction of Part I., "From a pathological oint of view, they (the diseases of sheep) are a perfect ine of wealth, are fraught with scientific problems of the ighest interest and importance, and are most suggestive of hat may turn out to be a new light on the pathology of any of the contagious and infectious diseases of man and ower animals."

---

1 *Manual of Diseases of the Eye.* By CHARLES H. MAY, M.D. New York, Chief of the Eye Clinic, Columbia University, &c., and CLAUDE A. WORTH, F.R.C.S. Eng., Ophthalmic Surgeon to the West Ham and East London Hospital, Assistant Surgeon to the Royal London Ophthalmic Hospital, Moorfields. London: Baillière, Tindall, and Cox. 1906. Pp 400. Price 10s. 6d. net.

THE fifth edition of May's Manual of Diseases of the Eye has been prepared by Mr. Worth. It preserves the high reputation which the book has already obtained. Like most of its competitors this manual has all the characteristics of a condensed text-book. In the process of condensation the author is liable to lose sight of the special requirements of students. Whilst the author of a text-book is justified in assuming some elementary knowledge on the part of his readers it is these fundamentals which require special emphasis and expansion by the writer of a manual. We regard it as a prime function of a manual to bridge the gulf between physiology and pathology. This is especially the case in ophthalmology, where the student is confronted with optical difficulties. Yet in the manual under consideration—and it is no exception in this respect—elementary optical principles are relegated for discussion to Chapter XXI. It is extremely illogical to describe for students the normal and pathological conditions of the fundus before teaching in detail the means whereby they can verify the descriptions for themselves. Another evidence of condensation is observed in the endeavour to crowd too much into the compass of the manual. This is noticeable not only in the mere mention of rare conditions such as simply confuses the student without adding to his stock of useful knowledge, but also, and in a more reprehensible manner, in the enumeration of many methods of treatment without proper indications for their use and of their respective advantages.

Apart from the general arrangement and insufficient discussion of elementary principles to which attention has been drawn May and Worth's Manual is a favourable specimen of its class. We may, perhaps, refer to a few details which might be improved in a future edition. Some reference should be made to the treatment of wounds involving the canaliculus. Whilst angular conjunctivitis and the diplobacillus of Morax-Axenfeld are both mentioned their relationship is not stated. We have been unable to find any mention of the so-called xerosis bacillus, though it is frequently present and cannot be diagnosed morphologically from the Klebs-Löffler bacillus. The palpebral and bulbar forms of spring catarrh are only exceptionally found combined. No mention is made of the rare cases of transverse calcareous film of the cornea in eyes with good vision; though the treatment given is applicable to these cases alone. A distinction should be drawn between posterior staphyloma and the myopic crescent. The suggestion of the use of a myotic in the treatment of some cases of iritis is inadvisable in a student's manual.

The illustrations are a special feature of the book—335 figures, including 21 coloured plates. They are for the most part excellent. Figs. 33 and 34 do not represent the ordinary appearance of lamellar cataract. The arrangement of vessels in Figs. 37 and 38 is unusual and in any case these figures should be turned round. The position of the lacrymal sac in Fig. 88 is inaccurate. Fig. 111 is not a good picture of episcleritis, nor is Fig. 171 an accurate diagram of a normal iridic angle. Figs. 179 and 180 of iridectomy and Figs. 188 and 189 of cataract extraction are reproduced from very successful photographs but diagrams on a larger scale would be more instructive.

Die Blinddarmentzündung in der Armee von 1880–1900. (*Perityphlitis in the Army from 1880 to 1900.*) By Dr. STRICKER. With ten plates. Berlin: August Hirschwald. 1906. Pp. 95. Price 4 marks.

THIS small volume consists of a report on all cases of appendicitis, or, as the author terms it, perityphlitis, which have occurred in the German army during the 20 years 1880–1900 and in addition a few statistics are given in regard to cases of the succeeding years, 1900–05. The number of cases brought under survey is very large, amounting to 6390, so that on this account alone it forms a very valuable contribution to the literature of the subject in regard to mortality and other statistics. On the other hand, it must be pointed out that these cases have occurred under very varied conditions of diagnosis and treatment and therefore the statistics in regard to them cannot be accepted with the same confidence as those involved in a series of cases under one surgeon or at one of our own hospitals.

From the total number of 6390 cases Dr. Stricker deducts 94, leaving 6296 cases. After a perusal of the reports of these 94 cases he comes to the conclusion that they presented no definite signs of inflammation and that they should be classed in the category of constipation or appendicular colic. They yielded readily to aperient treatment. The treatment during these 20 years has been essentially medicinal or expectant, operation only being resorted to in cases of definite abscess formation or general peritonitis; to that of the 6296 cases, only 235, or 3·7 per cent., were operated upon. The total mortality amounted to 270 deaths, or 4·3 per cent., but the mortality of the cases operated upon amounted to 28 per cent. The figures for the cases of appendicitis during the years 1900–05 compare very favourably with these and point to considerable improvement in the surgical treatment of the disease. Thus, the percentage of cases operated upon during this period rose to 14 per cent., with a mortality of 15·5 per cent., but it is pointed out that the mortality of the surgical cases varied for the different army corps from 0 to 34 per cent. The total mortality for all cases of appendicitis during this period 1900–05 was reduced to 3·1 per cent.

Although the author naturally regards with approval the improved surgical skill as evidenced by these figures, he is not in favour of adopting the more advanced surgical treatment in the army. He points out that whereas only 11·3 per cent. of the total number of cases were invalided out of the service, of the cases treated surgically 71 per cent. were dismissed as unfit. He admits that with more general surgical treatment this proportion would be considerably reduced but he thinks that it would still amount to at least 50 per cent., a supposition which appears hardly justified in the light of statistics from other sources.

In regard to recurrences, 276 or 4·4 per cent. of the cases had had attacks previously to their military service; 905, or 15 per cent., had recurrences during their service; and of 910 cases which he was able to follow up after leaving the service, 144, or 18·8 per cent., recurred, leaving 766, of which 92, or 12 per cent., suffered from chronic appendicular trouble and were in consequence rendered unfit for further service. More than half the recurrences took place within the first year. With such a large supply of data at his command Dr. Stricker is able to discuss with some effect the interesting question as to whether appendicitis is actually so much on the increase as is by some supposed. He has arranged a table showing in the successive periods of five years the number of cases diagnosed as appendicitis, liver complaints, stomach and intestinal diseases, and peritonitis. This table clearly shows that whereas there has been a steady and large increase in cases of appendicitis there has been a decrease in other abdominal cases in more than corresponding proportions and he is therefore led to the conclusion that the increase in cases of appendicitis is only apparent and due to a more accurate recognition and diagnosis of the disease. Many details are given in regard to the different exciting causes of the disease and the post-mortem findings, and they agree for the most part with those of other series of cases. The last chapter of the book is devoted to the question of the importance of a leucocyte count as a help to the diagnosis of suppuration and to the determination of surgical interference.

The Combined Treatment of Diseases of the Eye. By G. HERBERT BURNHAM, M.D. Tor., F.R.C.S. Edin., Professor of Ophthalmology and Otology at the University of Toronto. London: H. K. Lewis. 1906. Pp. 92. Price 3*s.*

THE "combined treatment" consists of hypodermic injections of pilocarpine, one-twelfth of a grain up to half a grain, together with the internal administration of mercury and iodide of potassium. The injections are given daily for from ten to 21 days. After an interval of from two to four weeks another series of from seven to ten injections is given. This series is then adhered to and kept up with intervals varying from four to eight weeks. The treatment can be continued for an indefinite time. As might be expected, the best results are obtained in syphilitic disease, but considerable improvement has been noticed in cases of iritis, iridocyclitis, and sympathetic ophthalmia. In many of the cases recorded insufficient details of the clinical history are given, and the reader is dependent entirely upon the author's bare statement of diagnosis. A regrettable tendency to regard the treatment as a panacea for all intractable diseases of the eye is noticeable, benefit being alleged in such cases as disease following masturbation, conical cornea, paralysis of the third nerve, hypopyon ulcer, "hyalitis," retro-ocular neuritis, albuminuric retinitis, and so on. We consider that the author is scarcely justified in appropriating this method of treatment in the manner he has done. It is a recognised mode of treatment in properly selected cases and the results which he has obtained are not so revolutionary as to merit a special monograph. The virtues of precision and perseverance in treatment are rightly emphasised, but though they bear repetition they are amongst the axioms of the conscientious practitioner.

LIBRARY TABLE.

Archives of the Middlesex Hospital. Vol. V. Fourth Report from the Cancer Research Laboratories. Edited by W. S. LAZARUS-BARLOW, M.D. Cantab., F.R.C.P. Lond. London: Macmillan and Co. 1905. Pp. 277.—This report from the Cancer Research Department of the Middlesex Hospital contains the records of much useful work, chiefly statistical and histological. The first part consists of a tabulated synopsis of the post-mortem examinations and operations on cases of malignant disease in the hospital during the year 1904, with details of the secondary deposits and the microscopical nature of the growth in all cases. There are also statistical studies of "cancer ages" and the site-incidence of carcinoma to which reference has already been made in a leading article.[1] Mr. W. T. Hillier contributes a note on three experimental inoculations of animals with considerable amounts of epithelium, but in each case the inoculated material was treated as a foreign body and no epithelial growth resulted. A histological study of considerable interest by Dr. G. T. Wrench deals with the relation of elastic tissue to carcinoma. He finds that the small-meshed intra-alveolar stroma of carcinoma, whether primary or secondary, is devoid of newly formed elastic tissue except in the neighbourhood of vessels or ducts. In the special instance of primary carcinoma of the liver he finds at least two varieties of stroma—a small-meshed form free from elastic tissue and a large-meshed variety containing abundant elastic tissue and indicating a pre-existing cirrhosis. These observations therefore throw some light on the cases of so-called cancer with cirrhosis. Dr. P. Campiche and Dr. W. S. Lazarus-Barlow contribute a paper on 1976 cases of malignant disease of the breast, which constitutes a most exhaustive study of the clinical and pathological features of the disease both in females and males. An interesting paper of similar character on malignant disease of the liver and bile passages by Dr. H. A. Colwell comprises statistics of 41 cases of primary carcinoma of the liver, 31 of the gall-bladder and bile passages, and 608 of secondary deposits in the liver observed in 12,500 necropsies, of which about 3300 were cases of malignant disease. Some information of very considerable interest is afforded, especially in regard to the frequency of gall-stones in cancer of the gall-bladder and bile passages, notably the rarity of biliary colic in that condition and the later age at which these cases occur in women than in men. The same observer contributes a short paper on the relation of carcinoma to gall-stones in which he states that the occurrence of gall-stones in cases of carcinoma in the two sexes is approximately proportional to the liability of males and females to cancer; that gall-stones are met with in both sexes approximately two and a half times as frequently in carcinomatous as in non-carcinomatous cases; and that the liability of gall-stones to be associated with carcinoma is independent of the seat of the primary growth. A monograph on Malignant Disease of the Prostate is contributed by Mr. J. W. Thomson Walker, *based on a very minute study* of 16 cases, a larger number than has been previously recorded. This paper constitutes a valuable addition to the literature of the subject and one worthy of note, since there can be little doubt that carcinoma of the prostate is more common than statistics show owing to the fact that the malignant nature of some of the cases is at present overlooked as a result of their tendency to be confined to the gland itself. The history, symptoms, and physical signs as observed in the cases forming the basis of the paper are carefully summarised and the histological characters of the various growths are described in detail in all the more recent cases. A paper on the x ray treatment of malignant disease is contributed by Mr. C. R. C. Lyster, in which the results of the treatment are recorded as observed in 46 cases. The indications for the treatment and its limitations are succinctly stated and critically considered. Mr. W. Sampson Handley records the results of a research into the manner of the parietal dissemination of mammary carcinoma in continuation of his previous work. He has studied microscopically sections of the skin around the breast and finds that the appearances obtained support the view of the centrifugal spread of the growth along the meshes of the deep fascial lymphatic plexuses, a process to which he has applied the term of "fascial permeation." A short paper by Dr. W. Gordon Taylor deals with giant cells in sarcomata, which he finds occur only in sarcomata connected with bone, with the single exception of one case of sarcoma of the parotid gland. Dr. J. J. Douglas records the results of a further study of the blood in malignant disease. An interesting, suggestive, and important paper by Mr. A. G. R. Foulerton deals with the subject of chondrifying carcinoma, with a record of three cases. A detailed bibliography is also appended. Mr. Foulerton discusses the nature of the process of chondrification in carcinoma and puts forward a bio-chemical theory to explain it. The paper affords a very notable contribution to a subject which is little understood. As a whole this volume represents good, solid work in the domain of cancer research and does great credit to the editor, Dr. Lazarus-Barlow, and his co-workers.

---

[1] THE LANCET, March 10th, 1906, p. 684.

Manual of Diseases of the Nose and Throat. By CORNELIUS GODFREY COAKLEY, A.M., M.D., Professor of Laryngology in the University and Bellevue Hospital Medical College, New York City; Laryngologist to Columbus Hospital, the University and Bellevue Hospital Medical College Clinic; Consulting Laryngologist to the New York Board of Health, &c. Third edition, revised and enlarged. Illustrated with 118 engravings and nine coloured plates. London and Glasgow: Henry Kimpton. 1906. Pp. 94. Price 14s. net.—The third edition of this book is well up to the standard arrived at in previous editions and shows, amongst other additions, a considerable increase in the space devoted to the treatment of the accessory sinuses of the nose. The third chapter contains a very full and careful description of the methods of examining the nose, the larynx, and the naso pharynx, followed by a short account of the instruments used. The fifth chapter is devoted to the causes of nasal obstruction and its symptoms. Diseases of the nose are then discussed seriatim, though the pathological anatomy is only cursorily dealt with. The appropriate methods of treatment in hypertrophic rhinitis best suited for the various pathological conditions found in this disease are given. In atrophic rhinitis Dr. Coakley has not alluded to the more recent forms of treatment; in fact, the only one which he advises is irrigation and the application of oil sprays afterwards. The treatment of this disease might well be brought up to date, especially in view of the admirable work which has recently been done by Moure in the subdivision of atrophic rhinitis. The author very correctly states that membranous rhinitis is not to be *confounded with nasal diphtheria, though it is sometimes* difficult to distinguish between the two. Malignant disease of the nose is very briefly discussed. The seventh chapter, that on the accessory cavities, is far superior, as we have said, to that in the previous editions and is now in keeping with the rest of the book. In peritonsillar abscess Dr. Coakley's incision is almost vertical, in contradistinction to that usually employed in this country which is nearly horizontal and which we consider superior. Diphtheria still receives a large amount of attention, though it seems questionable whether a description of diphtheria should be included in a book of this character. Tuberculosis of the larynx is also amply discussed, Dr. Coakley advocating a very conservative line of treatment and condemning the employment of tracheotomy if the patient is not likely to live for more than a few days; though it is difficult to see that such a view is compatible with the dictates of humanity. Paralyses of the various muscles of the larynx are presented by the author to the reader in such a way as to raise no suspicion as to the uncertainty which has existed as to their pathology. The work concludes with a full chapter on therapeutics, with a fair number of prescriptions suitable for the treatment of the various diseases discussed in the book. This is a handy little volume which will form a useful addition to the library of many general practitioners.

Transactions of the Medico-Legal Society for the Year 1904–1905. Edited by R. HENSLOWE WELLINGTON, Barrister-at-law, and STANLEY B. ATKINSON, M.A.Cantab., M.B.Lond., Barrister-at-law. Vol. II. London: Published for the Society by Baillière, Tindall, and Cox. Pp. 117. Price 5s.—The Medico-Legal Society is a comparatively new society but the number of its members is gradually increasing and it is likely to be productive of much useful work on the border-line of medicine and law. The present volume contains several papers of considerable interest and the records of the discussions which followed the reading of them. Dr. T. Claye Shaw contributes a paper on an Obscure Form of Alcoholism involving Irresponsibility. He points out that the connexion between drunkenness and crime is so immediate that every detail of the act should be well analysed with the view to explain the question of responsibility. He draws attention to one phase where the signs of inebriety were so masked (though the real loss of inhibition was intense) that only by a special consideration could a right conclusion be arrived at as to whether the individual was to be held responsible or not. If an individual has suffered from inebriety but has been cured the brain centres may resume their natural conditions. In some instances, however, complete recovery does not occur, though the patient may regain the power of the ordinary reflex brain functions to so complete a degree as to deceive those with whom he was usually in contact, whilst he might at the time be in a state of "minus inhibition" and be really dangerous to himself or to others. To the ordinary individual he would pass for a sane person, but he is really unfit for responsibility and his acts are more like those of a somnambulist or of *a person in* the stage of recovery from an epileptic fit. The Hon. Sir Joseph Walton contributes some interesting Notes on the Law of Evidence, in which he impresses upon his readers that the rules of reasoning and proof which are applied in an English court of justice are, speaking generally, the rules of ordinary logic and common-sense. Amongst other papers we may mention the following: The Definition of Accident, by Dr. S. B. Atkinson; the Law Relating to the Criminal Responsibility of the Insane, by Mr. A. D. Cowburn; Privileged Communications and

Professional Secrecy, by Dr. A. G. Bateman; and Degeneration, its Causes and Prevention, with Reference to the Proposed Sterilisation of Certain Degenerates, by Dr. R. R. Rentoul. Some of the above formed the basis of interesting discussions

Methods in Plant Histology. By CHARLES J. CHAMBERLAIN, A.M., Ph.D., Instructor in Botany in the University of Chicago. Second edition. London: T. Fisher Unwin; Chicago: The University Press. 1906. Pp. 262. Price 10*s.* 6*d.* net —The first edition of this book was published in 1901 and embodied the results of a course of histological technique conducted by the author in the University of Chicago. Since that time laboratory methods in plant histology have been much improved and as a consequence the present edition of the book will be found to contain more detailed information than its predecessor. It is divided into two parts—the first dealing with the principles of the preparation of specimens such as section cutting, staining, mounting, and so on; while in the second part these principles are applied to specific cases. This latter portion of the book will be found of particular use to the beginner, for the types selected are such that he will not only find useful practice in the methods of microscopic technique but will be able to form at the same time a satisfactory collection of specimens for study illustrating plant structure from algæ to angiosperms. The directions for collecting and growing laboratory material will also be found helpful. Full details are given with regard to the somewhat tedious Venetian turpentine method of mounting—a method, however, which has been practised with much success by the author and his students. He states that "the surprising beauty of successful preparations will compensate for the large proportion of failures which are likely to occur." The book is well illustrated. The curriculum of the medical student takes up so much of his time that he is not very likely to devote himself to a study of botany in its higher branches, but the book will at any rate prove useful for reference.

JOURNALS AND MAGAZINES

The West London Medical Journal.—The July number of this journal contains the Cavendish lecture delivered by Sir William Macewen on Some Points of the Surgery of the Lung in which the physiological doctrine that collapse of the lung takes place directly an opening of any kind is made in the pleura is combated and cases are quoted in which the lung remained in contact with the chest wall even after extensive wounds. An instance is recorded in which surgical interference in a case of pulmonary tuberculosis practically saved a patient's life. Under the heading of Proceedings of the Society is recorded an interesting discussion on influenza, dealing especially with the sequelæ and the complications of the disease,

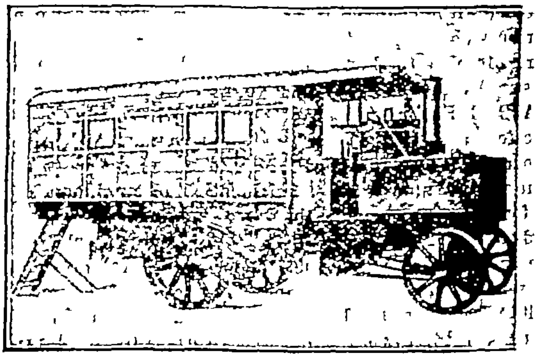
The Medical Chronicle.—The June number of this journal is devoted mainly to the subject of syphilis. It opens with a paper by Dr. W. Hale White on the Clinical Aspects of Visceral Syphilis, which is followed by one on the Present Treatment of the Disease, chiefly from a military point of view, written by Lieutenant-Colonel E. Butt, R.A.M.C. Continuous rather than interrupted administration of mercury is recommended, intramuscular injection being advised as the most convenient method, while local application of mercurial preparations is deprecated. Dr. G. H. Lancashire writes of tuberculous and syphilitic affections of the face. A brief note, by Dr. I. Walker Hall and Dr. J. Randal Hutchinson, points to the inefficacy of such drugs as ammonium hippurate, citarin, and thyminic acid in controlling the endogenous uric acid in gout.

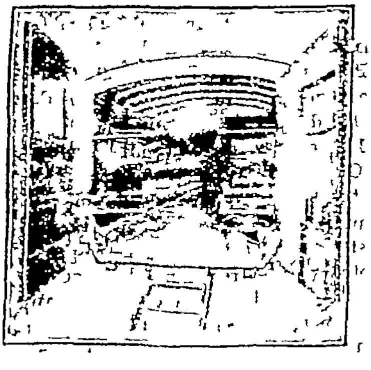
The Bristol Medico Chirurgical Journal.—The June number of this journal contains three articles of gynæcological interest. Dr. E. W. Hey Groves writes on the structures forming the pelvic floor and on the relation of pain to pelvic displacements; Mr. C. Hamilton Whiteford on diagnosis and treatment of tubal pregnancy; and Dr. Eliza L. Walker Dunbar on the new theory and prophylaxis of eclampsia. This last article is in commendation of thyroid extract as a prophylactic measure and as a remedy after symptoms have set in. Dr. I. Walker Hall records some new methods of clinical pathology, including modes of examining gastric contents, urine, and fæces.

New Inventions.

THE "RASTILON" AMBULANCE SPRING.

Messrs. J. and A. Carter of Great Portland-street, London, W., have fitted to some ambulances built for use in the service of the Portuguese Government over rough roads in connexion with a military expedition in West Africa, a specimen of which is shown in the illustration, a new spring which they have invented and named the "Rastilon" The springs are mounted in a circular box and connected with iron rods carrying the stretcher. The circular box protects them in a great measure from atmospheric influence and they are so constructed as to adjust themselves automatically to the weight which they may be carrying. Their resiliency is very great whether that weight be 8 or 18 stones while at the same time there is practically no oscillation. The ambulances are probably the largest that have yet been made. Each contains eight stretcher beds and there is ample provision for attendants. The steam lorries which carry the bodies of the ambulances are of a particularly heavy make, weighing five tons each. The driving engines are of 45 horse-power. The lorries are made interchangeable with freight-carrying wagons for store haulage. Of course, the testing of springs on the floor of a workshop is a different thing from testing them in actual use but if they bear out the claims that are made for them by the inventors in the rough country of West Africa their adoption for ambulance work in our own and other countries will be very desirable.





THE LANCET.

LONDON: SATURDAY, JULY 28, 1906.

"Christian Science" and the Death of Major Whyte.

THE Attorney-General has ordered that a *nolle prosequi* should be entered in the case of Mr. GEORGE ROBERT ADCOCK, formerly a medical practitioner and still upon the Medical Register, who was recently put upon his trial for manslaughter at the Old Bailey, with the result that the jury disagreed as to his conduct. The course thus taken will evidently commend itself to Mr. Justice BIGHAM who conducted the lengthy trial referred to, for he intimated his opinion upon the subject to counsel representing the prosecution soon after the jury had failed to arrive at a verdict, and there is no reason to believe that his lordship's estimate of the law and evidence was not in every way correct. Mr. ADCOCK was tried not as a "Christian Scientist" who had assisted at the bamboozling of Major WHYTE, and who, by holding out delusive hopes of restoration to health by means of "Christian Science," had brought him to a lingering and a painful death; he was charged with manslaughter on the ground that, standing to Major WHYTE in the relation of medical attendant, he had failed to exercise care, attention, and proper skill towards him, in consequence of which his patient had died. Had the jury been able to arrive unanimously at the conclusion that the accused was called in and had acted as the deceased's medical attendant the second portion of the question propounded to them would probably have afforded them little difficulty. That point, however, is not under discussion; but the general circumstances of the case demand some notice from us apart from the unsatisfactory legal result.

We need not recite the circumstances which led up to Major WHYTE falling into the hands of the "Christian Scientists" or describe the "treatment" meted out to him by others besides Mr. ADCOCK. They are familiar to any of our readers who may be interested in the case from the reports of the inquest in the daily newspapers, and they have been briefly referred to in THE LANCET. It is enough to say that the "treatment" so far as Mr. ADCOCK was responsible for it, was such that, had he been acting in the capacity of the patient's medical attendant, he would have deserved, and doubtless would have received, very severe punishment. It seems, however, to be tolerably clear that although there was evidence that those nearly related to Major WHYTE knew the accused to have been a qualified practitioner, and were basing hopes upon this, the patient himself did not so regard Mr ADCOCK and did not employ him as his medical attendant, but, on the contrary, would have refused any treatment inconsistent with "Christian Science." At all events there was sufficient doubt in the eye of the law as to the guilt of the accused to justify the division of opinion in the jury which tried him, and a second trial upon the same facts was thus made undesirable. The result of the case is not encouraging to those who see with regret lives needlessly sacrificed, but at all events it makes the situation clearer. Mr. ADCOCK could not be convicted and the other persons censured by the coroner's jury which found a verdict of manslaughter against him cannot be prosecuted. Captain BAYNES, Mr. SMITH, Mrs. GRANT, and all those, from Mrs. EDDY downwards, who are morally responsible with them for such deaths as that of Major WHYTE, are safe, so far as the criminal law at present stands, from conviction for manslaughter. If, however, we are satisfied that the law has no power to punish those who act as the accused acted and as those of like thinking would act, it does not follow that we need regard the law as satisfactory, however difficult its amendment may be. If a medical man's patient dies, and there is evidence that he has been wrongly treated, the medical man may be put upon his defence: he may be convicted and punished, or may be acquitted, according to the degree in which want of skill and care on his part has contributed to the death. If a foolish or designing person, who has abandoned Christianity and has avowed a disbelief in science, calls himself a "Christian Scientist" he may pretend to heal disease by a mumbo-jumbo the absurdity of which places it beyond the reach of reason; yet when his victim dies the law cannot touch the "healer" or the propagandist who has paved the way for him. If a needy and unscrupulous woman rents rooms in the fashionable quarters of great cities and cajoles other women more foolish than herself out of a few sovereigns by the pretence of "telling their fortunes," she may be fined; if a wandering gipsy obtains shillings from servant-maids by similar devices, the "fortune-teller" can be, and is, fined or imprisoned. But as the law stands apparently the "Christian Science healer" can cozen his victim out of life itself by falsely pretending that he has the power to cure disease, and can earn a living by doing so with perfect safety—to himself.

Legislation to meet such a case presents grave difficulties, and the question at once arises for practical persons as to whether such difficulties should be faced or whether we should regard the loss of life which results from "Christian Science" as so trifling that it may be treated as a negligible quantity. The deaths may not be very numerous; "Christian Scientists" are not quite as whole-hearted fanatics as the members of the sect known as the Peculiar People. "Christian Scientists" avoid the awkward consequences which follow the manslaughter of a child through the withholding of medical aid from one not old enough to summon it; and we should probably hear more often of the absence of a medical certificate when adult "Christian Scientists" die if they always unflinchingly carried their professions into practice in the face of great pain or of imminent danger to their lives. Nevertheless, instances of deaths with inquests, and sometimes with abortive prosecutions following them, have been sufficiently numerous during the past few years for the matter to be worthy at least of serious consideration, and the case of Major WHYTE may be taken as illustrating the difficulties to be encountered. He was a man in the prime of life, 44 years of age, an officer in the army who had earned the Distinguished Service Order, and who, unless we assume that the accident which had befallen him and the suffering which had ensued had affected his mental capacity, might assuredly be regarded as one able to guide himself in the ordinary affairs of life. *Is it not possible to interfere directly with such a person if he has once fallen under the influence of "Christian Scientists," covetous of those emoluments which are to be derived from treating a patient able to pay, and perhaps in equal degree ambitious to acquire and to display their baneful control over a fellow creature?* It seems to us that it is not easy to promote the exercise of such interference. It is true that we punish an attempt at suicide, although the person who wishes to destroy his own life may protest that he has a right to do so. The case is not analogous. We do not, however, punish those who merely imperil their lives by acts which, however foolish and dangerous, have usually been regarded as lawful. To exercise any interference by means of argument or instruction is, of course, out of the question. Take the case of Major WHYTE as an example. No one would attempt to reason with persons who would wash their sound bodies with soap and water (as we will credit the aristocratic converts to "Christian Science" with doing) but who would decline to allow a suppurating wound to be washed with those cleansing agents which take the place of soap where dirt, less easy to remove than that which adheres to the surface of the skin, has to be dealt with. It is not possible to argue with people so blind to the ordinary conditions of health and disease. The medical treatment, which might have saved the life of Major WHYTE after his bedsores had developed, would have consisted to a large extent in carrying out with scientific completeness those principles of cleanliness which commend themselves to the good sense of all civilised human beings in the present day. If, however, we cannot legislate directly for the benefit of such persons as may fall into the hands of the "Christian Scientist," and if reason cannot be applied with hope of success either to the patient or the "healer," it may still be possible to deal with the latter as with one who deceives others by false pretences to the danger of their lives, or, in other words, as one who pretends to the title of "healer" without being qualified to heal. The legislature has recognised in the recent Midwives Act a principle which many hope to see extended some day, so as to protect a wider public. In a few years' time no woman will be able to practise as a midwife for gain who has not qualified by actual learning as a midwife, in addition to being registered as such. The purpose of legislation here has been to protect the lives of the public from pretenders to exact knowledge; and in another column of this issue of THE LANCET (p. 249) will be found a brief article showing the valuable work that is done under the Midwives Act. If those who pretend falsely to be able to heal others are rendered legally punishable, deaths under "Christian Science," and under many other forms of charlatanry and quackery, will cease to a considerable extent.

Old Houses in the Country.

IT is an unfortunate [illegible] canons of art and of hygiene are so rarely [illegible] The [illegible] garments are [illegible] ysician, the [illegible]

by a miasmatic atmosphere, and in the same way a house that presents every charm to the eye may have defects which no sanitarian can overlook, even if they do not render it an unsavoury object to the nose. At the present time of the year, when so many people are about to take their annual country holiday, this question of the healthiness of country houses becomes unusually interesting and important. The present preference for old things in matters of art extends also to the choice of country houses. People are paying huge prices for Chippendale chairs, and they are prepared to be equally extravagant for houses and cottages belonging to the same or an earlier period. It is worth while to pause for a moment and to consider whether a beautiful appearance may not be too dearly bought in the matter of houses. A lovely exterior is well enough but the unromantic drains are of more importance. All educated persons know this nowadays and to utter a word of warning against the undue value often given to the one and the lack of consideration bestowed upon the other may seem unnecessary. But knowledge does not keep the world from foolish actions when fashion, the lust of the eye, and similar powerful impulses are at work. It is natural enough that when a man chooses a house in the country the general aspect of the residence should largely influence him. Caught by a pleasant situation, by old walls and creepers and mellow tiles, by convenient accommodation and accessories, the man who is taking a house for his family's country holiday is likely to lose sight of the unobtrusive drainage system. He knows that he ought to make inquiries upon the subject and probably he does so in a perfunctory way, but what he does not know is that habitation of a certain kind of old house must be attended with risk. A good drain is a good thing but it will not counterbalance all the unhygienic disadvantages of warped, imperfect flooring, attics and garrets loaded with the dust of ages, dark corners, and noisome cupboards. Yet too often the beautiful Queen Anne or Georgian house has all these drawbacks and the paterfamilias who hires it may be but poorly rewarded for his expense if the stay in the country instead of resulting only in rosy cheeks and renewed appetites bestows upon his household an affliction of sore-throats, or worse, of diphtheria, or typhoid fever. We are not conjuring up imaginary terrors, for we speak with the recollection of concrete instances that doubtless many of our readers can match only too fully. In fact, nobody would try to deny that there are many old houses where sanitation, disregarded according to our modern notions when the mansion was built, has never been allowed to come into its own. That such was the case with some of the great country seats of England has been clearly shown in several instances which are now historical. Striking examples were afforded by that outbreak of typhoid fever at Windsor which robbed England of Queen VICTORIA'S Consort and by that other attack which so nearly cost the country her present beloved Sovereign. Windsor Castle has since been put in thorough sanitary order, but some of our most famous palaces cannot be so treated, at least in a satisfactory manner, their whole fabric being opposed to genuine hygienic treatment.

Grave drainage defects are naturally, then, to be found much more commonly in old houses, and it is just old houses that at present all the world is looking for when it seeks a country holiday resort. Country air is an excellent thing and to live in a beautiful house is conducive to good health, as every constant source of pleasure and of peace must be, but an old house takes a lot of overhauling and if it is not thoroughly overhauled its beauty may be too dearly bought when to its æsthetic charm are added its leaking pipes or its ineffective water-closets. Too many old houses in the country rely for their drainage upon a water system that will not stand the test of a thorough examination. As is the case with so many other matters, a complicated system imperfectly carried out is worse than a simpler method properly executed. It is far better to have earth closets than water-closets imperfectly flushed. And it is the latter that are far too frequently to be found in the country. Again, inefficient means for the disposal of kitchen refuse and of bath and bedroom waters are only too often to be found in old country houses. and the pity of this is the greater in that with proper arrangements a valuable manure is forthcoming from these various quarters. The well-drained house should never be a possible source of infection to its inmates, but it should, in fact, become a centre of nourishment and of support to its neighbouring vegetable, fruit, or flower garden. Our excellent contemporary the *County Gentleman* remarks in a recent article, which has drawn our attention to the subject of country houses, "Intelligent people on coming down to the country ought to be ashamed of fouling ditches and little water-courses by a crude and lazy system of drainage; the proper destination of kitchen wash and slops is the vegetable garden." This is another of the things that is well known to all educated people and yet how seldom is it carried into practice in England.

We have alluded chiefly to the question of taking a house in the country for a short term of residence partly because this phase of the question is topical and partly because when an old house is purchased nowadays it is usually put into as complete sanitary repair as possible. Not always, however, and our remarks apply with point to those who purchase or hire for a long term an old country house for habitual week-end use. Habitation being fitful the same thorough re-drainage does not always occur. The temptation to take a picturesque house or cottage—and to risk the drainage—is, in these circumstances, strong upon some. It is, in fact, a very costly matter to make really healthy homes of these old cottages and houses. When the walls and roof have been properly attended to, when the drainage system has been thoroughly renovated or installed anew, when the floors and ceilings have been purged of "undesirables," and when baths have been added, an amount of trouble and money will have been expended that would have gone far towards placing a new house upon the desired spot. We willingly admit our admiration of old houses and picturesque cottages, but when it is a question of living in them, even if only for a few days at a time, we hold that their hygienic perfection should be the first thing to be considered. Theoretically the public holds exactly the same view, practically they allow their sense of the picturesque to get the better of their reason. They allow themselves to believe that a little tinkering here and there will set right an absolutely unhealthy fabric.

◆

Official Regulations and Professional Secrecy.

IN another column we publish a letter from a correspondent in India in which are raised questions affecting the relations of a medical man holding an official position which are of importance firstly to his patients and secondly to his official superiors and perhaps to the official superiors of the patients. Our correspondent desires our opinion upon these points and all must agree that the matters at issue are of the sort that require careful deliberation. It must be remembered that many problems in medical ethics resemble the unsolved problem of three bodies in dynamics, the extent and results of whose mutual attractions cannot be estimated. The relation of the medical man to the patient is clear, the relation of the medical man to his superiors is also clear, but the inter-relations of all three are most complicated. The solution of the problem must therefore be sought along the lines of that peculiarly British mental attribute—compromise.

The first question asked by our correspondent relates to the duties of a medical officer towards a regimental officer reporting himself sick with some complaint to which a certain amount of shame attaches—e.g., gonorrhœa. Medical officers have to fill up two classes of forms concerning both men and officers reporting sick. The one class necessarily contains full information upon the case and is sent in to the Medical Department of the army, whether it be the Indian Medical Service or the Royal Army Medical Corps. The other, which reports the weekly state of the case, goes to the commanding officer for his information. It is not supposed to be a confidential document and is liable to be seen by other officers and by orderly room clerks and the like. Spaces in the form are provided for the names of patients and for their diseases. Our correspondent asks his question as concerning officers alone, but we may say at once that his duty as a medical man is exactly the same whether his patient be an officer or a private. To a medical man all patients are equal. As disease is no respecter of persons, so a sick man is to his medical adviser merely a patient, and the laws of professional honour as regards secrecy are the same in all circumstances. The nature of the disease should be a matter solely between the medical officer and the patient, whatever the patient's grade in the service, and if only the medical officer and his patient were in question the matter would be comparatively simple. But here the third party to the problem comes in—namely, the authorities whose regulations lay down rules for the conduct of the army. It is obviously impossible for the medical officer to satisfy his duty to his patient and to the superiors of both himself and the patient, for on the one hand silence is demanded of him and on the other speech. The direction which compromise might take is at once indicated. We do not presume to lay down any rule for the conduct of the medical officer, for of course he must obey the regulations unless it is generally understood that he will not be found to blame for any technical infringement of them. We should say that the medical officer might very well consult the commanding officer as to the desirability of leaving the disease column blank in the report of the weekly state, which is copied in the orderly room, while at the same time he might, if required, hand in a private report to the commanding officer in which the disease column was filled up. If the commanding officer refused to allow this procedure the medical officer would have his choice of two courses. He could, having satisfied his medical conscience, carry out the regulation of the service to which he is bound or he could throw up his commission.

A second point raised in the letter to which we refer is as to what a medical officer should do when a regimental officer insists upon employing him and a civilian medical officer separately during the same illness, neither medical man being told that the other is attending. In this case the answer is more easy to give. The medical officer attached to the regiment should on learning the facts of the case lay them before his superior—i.e., the principal medical officer or before the officer commanding the regiment. In such a case it is probable that the medical officer would be relieved by his official superiors from the duty of professionally attending the regimental officer, although the former would still be bound to enter the name of the latter upon the official sick list. Practically speaking, we believe that medical officers as a rule find no difficulty in carrying out their work in conformity with the regulations; but, as we have said above, no hard-and-fast rules can be laid down for any general scheme of conduct. Each case of medical ethics must be treated on its merits and in cases where official duties clash with what would seem to be rules of professional secrecy PETER SIMPLE'S remark to Captain SAVAGE may be borne in mind. "Whoever heard of confidence between a post captain and a midshipman?" said Captain SAVAGE. "No, sir," replied SIMPLE; "not between a post captain and a midshipman, but between two gentlemen." A young medical officer may find himself torn between his duty as a medical man to his patient and his duty to his official superiors as laid down in the regulations. He will, we are sure, always find his regimental commanding officer, his principal medical officer, and his brother regimental officers ready to help him to the solution of hard problems, not as his official superiors but as comrades, and he will not do wrong if he consults them and asks their help.

INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND.—Of 14 candidates who entered for the Intermediate Examination held in July the following nine passed: L. C. W. Bonacina, W. R. S. Ladell, D. J. Law, W. M. Seaber, B Sc. Lond., P. Statfield, J. M. Weir, M.A., B.Sc. St. And., W. A. Whatmough, J. M. Wilkie, B.Sc. Lond., and C. H. Wright, B A. Cantab. In the Final Examination for the Associateship (A.I.C.), of three examined in the branch of mineral chemistry, two passed: J. W. Agnew and I. M. Heilbron; of three in the branch of organic chemistry, two passed: R. Le Rossignol, B.Sc. Lond., and G. W. Monier-Williams, M.A. Oxon., Ph.D. Freiburg; and of eight who entered in the branch of the analysis of food and drugs, and of water, including an examination in therapeutics, pharmacology, and microscopy, the following six passed: J. G. Annan, B.Sc. Lond., C. T. Bennett, B.Sc. Lond., G. W. Glen, F. W. Harris, E. H. Merritt, B.Sc. Lond., and F. Tattersfield.

Annotations.

"Ne quid nimis."

THE PROPOSED UNION OF LONDON MEDICAL SOCIETIES.

ANOTHER step towards the proposed union of London medical societies has been taken since we last referred to the matter[1] and we now have before us the report of the organising committee. This report has been printed after amendment and adoption by the general committee of representatives of the societies and it should now receive the close attention of all individual members of the various societies. The societies are invited to consider the report, and if they approve of the scheme as therein drawn up, to appoint representatives upon a new committee. This committee, together with the Presidents of the Medical Society and the Royal Medical and Chirurgical Society, will form the first council of the new society. The report shows clearly that very careful financial investigation has been carried out and we do not think that the organising committee has included any unwarrantable hypotheses in its estimate of the financial position of the proposed new society. Many difficulties of very various kinds have, we know, been met in the course of the proceedings which have culminated in this report. All the different societies concerned have had, and must have taken, full opportunity of pointing out the obstacles to the success of the scheme. That such wide freedom of discussion in a matter of this kind should be encouraged was, of course, the only manner in which a sound ultimate success could be achieved. It says much for the perseverance, energy, and capacity of the organising committee that so definite and tangible a project should now be before us, and it will, we think, be matter for deep regret if the one or two remaining opponents cannot see their way to reconcile the best interests of their societies with the best interests of the profession in London at large, and these are undoubtedly most to be served by amalgamation. We need not repeat the arguments which we brought forward in favour of the scheme so long ago as July, 1905.[2] None of much weight have been urged on the other side, the only obstacles arising from comparatively small and individualistic considerations. We do not believe that in such a way members of a profession, which of all others should be by its nature and training open to wide and liberal views, can be deterred from a step that is certain to conduce to their dignity, their advancement, and their convenience. Our lady colleagues, whose case presented at first one of the most awkward problems in the scheme, have set a good example. They are coming in as members of those sections which correspond to societies which at present have women members, and are leaving the question of Fellowship for the future to decide. The scheme as outlined in this report contains just provision for the actual demands of those bodies that will contribute property, money, a library, or a museum to the common possession of the new society. A finance committee will be formed on which will be represented, as is especially stated, each of those bodies which are bringing in funds. As regards libraries we may point out that Fellows or members of the Medical, Obstetrical, Odontological, and Ophthalmological societies are to have the privilege of using the library of the new society without payment of the annual library subscription. Perhaps the next most difficult question with which the committee had to deal was that of the publication of the proceedings of the various sections. There are some societies the published transactions of which form the chief attraction in the case of many members. This applies particularly, of course, to those societies the membership of which is to a large extent a country one. We may instance the Society for the Study of Disease in Children and the Society of Anæsthetists. In the case of both these bodies much pains have been bestowed upon, and great value has been attached to, the yearly volumes of "Transactions." Members of such societies need not fear, it seems to us, that they will in any way be losers if the proposed amalgamation comes into force. The monthly publication which is alluded to in the report should adequately fill the place of the specialist "Transactions." Reading the report, as we have done, in a critical spirit we find little to cavil at, and we look forward confidently to the materialisation of the scheme when the societies have once more considered the matter in detail and have nominated their representatives.

---

JUVENILE SMOKING.

NOW that the evils of smoking by juveniles are acknowledged by a *Select Parliamentary* Committee it may be presumed that some endeavour will be made to stop the sale of tobacco and cigarettes to children below a certain age. Two Bills drafted with this end in view were submitted to the consideration of the committee which agreed with the aims of both that introduced by Lord Reay and that drafted by Sir Ralph Littler, K.C., but the members concluded that the latter was the more workable of the two. They therefore were led to recommend that legislation should proceed on the lines of Sir Ralph Littler's Bill, to which, however, they suggest that certain important additions should be made. It cannot be supposed that the proposed measure will operate smoothly or that its provisions will reach all offenders. The utmost that can be hoped for is that it may be able to deal with particularly flagrant cases. The age limit, for one thing, will be certain to give rise to difficulties. In Sir Ralph Littler's Bill it is enacted that the person who sells or delivers cigarettes (the use of this word implies the giving of a cigarette to be an offence) to any child under the age of 16 years shall be liable to a penalty, and further that every child under the age of 16 years who shall be found in possession of cigarettes or found smoking tobacco in any form shall be liable to a similar penalty. It will be admittedly therefore a good defence if the age is proved to be above 16 years but in an addition to the Bill suggested by the committee it is provided that "police constables should be empowered to stop all youths *apparently* under 16 seen smoking in any public place and they should also be allowed to confiscate any tobacco found upon them." We have put the word "apparently" in italics as its retention might lead to distinctly unjustifiable proceedings. There are scores of youths surely who are over 16 years of age and who might even be 18 years of age, who, nevertheless, are "apparently under 16." The same word is used again in a further clause added by the committee which is as follows: "The Act should apply to all children apparently under the age of 16." The use of the word "apparently" in the clauses of any Act in which limits are laid down is calculated to render its successful administration very difficult. We should think that such a word has a too indefinite meaning for employment in a statute. We can, however, well understand the object of using the word; the police and the public are asked to differentiate broadly between "the little nipper"—the undeveloped boy—and the youth who is well on the road to manhood. It would be better therefore, we suggest, if the word "apparently" could be replaced by the word "obviously." It is of no use attempting to differentiate too finely in this matter. Lastly, there will be a difficulty in regard to the suggestion that the juvenile purchaser of tobacco in any form, who is genuinely employed by his father to fetch tobacco for him, should be exempted. If legislation is seriously demanded in this matter and is to be effectual no such exemption can be admitted. No child under a certain age is allowed to be supplied with drink at a public-house for the purpose of carrying that drink to his parents' home and though the associations of the public-house are not comparable with those of tobacco shops, yet for the purposes of the Act there seems to be no difficulty in meeting this provision nor is there any particular hardship forced on anyone. There can be little doubt that smoking in the case of juveniles is an evil and where it exists every endeavour should be made to suppress it, but that this can be effectively done by statute we have little confidence. The youth who smokes is, as a rule, not without a knowledge of the subtle ways of the world and the devices of unprincipled men, and in a great number of cases he will be encouraged to pursue his pernicious habit in a surreptitious manner as soon as the law prevents him from smoking in the present unchecked and open way. He is generally the wicked sort of boy who will likely enough find greater zest in smoking when he realises that he is setting the law at defiance at the same time. In a word, the Juvenile Smoking Bill does not reach the root of the matter. The moral training of the class of small boy who smokes wants considerable strengthening and above all parents should be brought to feel a stronger sense of responsibility in regard to their duties to their offspring than they have shown in the past.

THE DECHLORINATION TREATMENT OF DROPSY.

IN the *Scottish Medical Journal* for February Dr. F. D. Boyd has called attention to the value of the dechlorination treatment of dropsy—a method which we owe to the French and which has had little vogue in this country. Widal pointed out that in renal disease when sodium chloride accumulates in the body œdema results and albuminuria increases. On the other hand, when sodium chloride is withheld from diet the albuminuria diminishes and œdema may disappear. Dr. Boyd relates the following striking example of the value of this treatment. A man, aged 57 years, was admitted into hospital with swelling of the legs, the abdomen, and the hands. For 25 years he had suffered from attacks of bronchitis every winter. Ten years before admission he first noticed swelling of the ankles. In the last four years he had suffered from frequent attacks of dyspnœa and had seldom been free from œdema of the legs. For three months he had been confined to bed. On admission there were bronchitis, general anasarca, ascites, considerable effusion into both pleural cavities, and dilated heart. The radial artery was thickened and the blood pressure was low. The urine was scanty and contained albumin but no formed elements were found. A light diet and one and a half pints of fluid were given in the 24 hours. During the next six days the œdema slightly increased and the arterial pressure rose. Then a salt-free diet, consisting of bread made without salt, meat, fish, and fowl cooked without salt, and potatoes cooked without salt and eaten with fresh butter, was prescribed. The amount of fluid taken was kept at one and a half pints in the 24 hours. On the second day improvement began; the arterial pressure fell, and the quantity of urine more than doubled. Diuresis was maintained until all œdema had disappeared. The intake of chlorides on this diet was about two grammes in the 24 hours. There was an enormous excretion of chlorides which followed closely the excretion of water. The weight of the patient fell from 190 to 132 pounds and in 17 days he became free from the œdema, which had lasted for years. Cryoscopy showed a marked depression of the freezing point of the blood, indicating renal inadequacy. The blood contained 0·58, fluid taken from the legs 0·75, and fluid taken from the chest 0·74 per cent. of sodium chloride. The latter figures are excessive. The amount of chloride in the blood remains fairly constant. When chloride is taken in excess of the excretory powers of the kidneys it accumulates in the tissues and œdema results. When chloride is withheld from the diet the converse occurs: chloride passes into the blood and œdema disappears. Of course, other factors are concerned in the production of dropsy. Yet frequently, even in dropsy resulting from grave cardiac and renal disease, Dr. Boyd has seen œdema disappear on withdrawing salt from the diet when all other means failed.

THE RECOVERY OF RESIDUES FROM BRINE AND THEIR UTILISATION IN THE ROUTINE TREATMENT AT SPAS.

IN an interesting communication which we have received from Mr. F. Bale of Droitwich he points out that at Droitwich and other places in this country where the manufacture of common salt is carried on there have been thrown away for centuries or practically made little use of some of the best constituents of the brine. The ordinary scale which is produced in the evaporating pans together with the mother liquor which contains mineral constituents more soluble than common salt, such as magnesium chloride and sodium sulphate, can be utilised, he states, for the production of excellent mineral waters for drinking and other purposes, thus adding an important detail to the equipment of the health spa. The mother liquor may contain, according to the degree of concentration, as much as 25 per cent. of the sulphates of calcium, magnesium, and sodium. If this mother liquor is diluted with water and "salt scale" is added a mineral water is obtained, effervescing, he says, with oxygen. The disengagement of oxygen is singular and apparently proceeds from the dissolution of the hydrated sulphate of calcium which is the chief constituent of the "salt scale," although no chemical explanation of this production of oxygen gas is forthcoming. The evolution of gas is steady and goes on slowly for days, ultimately saturating the water. We presume that Mr. Bale has satisfied himself that this gas is oxygen as its development is a little difficult to account for. He regards the mineral water so obtained from these concentrated constituents of the brine as approximating in composition to the waters of many celebrated spas, while he attaches an added value to it owing to the surplus of oxygen gas with which it is charged It follows, he thinks, that the districts of this country which possess brine baths may now also possess that which they require as a necessary adjunct to balneotherapy—a medicinal water for drinking. Moreover, a water evolving pure oxygen gas is not likely to contain organic impurities and conceivably oxygenated water may supply a therapeutic need.

THE WILL OF MR. ALFRED BEIT.

THE late Mr. Alfred Beit in his will dated April 18th, 1905, records that he was a naturalised British subject living in England. The provisions of the will show that the testator was a man of broad ideas and one who had the welfare of his fellow men actively at heart. Nor are the bequests tied down by conditions which in after years might become onerous or impossible of execution. For instance, he leaves his estate of Borstler Jäger, near Hamburg, to be held in perpetuity for ever for the benefit of the people of Hamburg and Gros Borstel, intact and unbuilt upon, but should the authorities of the city find this impracticable they may, after 20 years from the date of the testator's death, realise the whole or part of the property and may apply the proceeds to charitable, educational, or public purposes for the benefit of the State of Hamburg. Among other bequests specially interesting to the medical profession are a sum of £20,000 to the Central Institute of Medical Sciences Fund, London University, £20,000 to King Edward's Hospital Fund, and £20,000 to Guy's Hospital. A remarkable bequest which may have a far-reaching influence upon the health of present and future generations in Africa is one of £1,200,000 for methods of transmission, such as railways, telegraphs, and telephones in connexion with the Cape-to-Cairo Railway. It is only necessary to read the record of African travel to see how the formation of a railway will do away with the appalling loss of life which occurred among past travellers, whether among themselves or the carriers of baggage. It is true that the opening, or at least the construction, of a railway through hitherto unopened territory is often accompanied by the spread of such diseases as malaria or yellow fever, but these can be guarded against. But once the railway is opened trade communication is rendered rapid and easy. Altogether the will is a striking example of how the possessors of great wealth may be benefactors of their species.

A YEAR'S WORK IN THE GOVERNMENT LABORATORY.

THE report of the principal chemist (Dr. T. E. Thorpe) upon the work of the Government Laboratory for the year ended March 31st, 1906, was published last week. In the Customs branch of the laboratory the total number of analyses and examinations made during the year was 52,140 as compared with 49,751 in the preceding year, being an increase of 2389. In the Excise branch of the laboratory the number of analyses and examinations made was 106,799. In the preceding year the number was 88,757, so that an increase of over 18,000 occurred, which was due mainly to the large number of samples of offal tobacco submitted to examination in accordance with the regulations under which such tobacco is presented for drawback. The number of samples of food and drugs referred to the Government Laboratory under the Sale of Food and Drugs Act was 101, against 109 last year. In the case of 100 samples so examined the conclusion of the Government analysts differed from those of the public analyst in ten instances (i.e., 10 per cent.). In the previous years the conclusions differed to the extent of 9·5 per cent. and in 1904 to the extent of 14·4 per cent. Public analysts are thus to be congratulated on the generally high standard of their work and Dr. Thorpe has contributed to this result by adopting uniform methods of analysis and making them known. The result is all the more satisfactory when the small number of referred samples is compared with the many thousands usually examined in the public service which are not so referred. It is interesting to note that the Government chemist agreed with the opinion given by an analyst in one case to the effect that a sample of brandy had been mixed with spirit which was not brandy. In the Customs department there was a considerable increase in the number of samples of enumerated spirits examined, due chiefly to spirits being entered as "brandy," the correctness of this description being questioned by the landing officers. In a number of cases the spirits did not correspond with the genuine brandy of commerce and were accordingly charged at the higher rate as unenumerated spirits. It is gratifying to see that at last the Excise authorities are turning their attention to the discrimination of spirits in the way indicated and we may be pardoned for claiming that we are the authors of this reform by our exposure of the adulteration of brandy with foreign spirit. The practice of filling chocolates with a strongly alcoholic liqueur appears to have been abandoned, as out of 44 samples examined a considerable number was practically free from spirit. As regards tobacco, liquorice and glycerine appear to be the chief foreign ingredients added, which agrees with our own statements on the subject. Other substances found were logwood and paraffin wax, neither of which, of course, is poisonous. 19 samples of cigarettes were found to contain percussion caps and in one gunpowder was found. These were doubtless added to assist the combustion of the tobacco but it may be pointed out that nitrate of potassium is frequently a normal constituent of tobacco leaf. There seems to be an increasing importation of "skim-milk" cheese which comes chiefly from Holland. In one instance the cheese contained only 3·3 per cent. of fat. An interesting observation was made in regard to the examination of certain fishes taken from a river which was believed to have received the arsenical drainings from a mine in its vicinity. Arsenic was found to be present in the fish, and in another instance salmon peel taken from a stream at Lostwithiel, and supposed to have been poisoned with copper from mine drainage, were found to contain an appreciable quantity of copper. Altogether the annual reports from the Government Laboratory are invariably full of matters of interest to the nation and the one just issued is no exception.

DIAGNOSIS BY SMELL.

THE very interesting letter from Dr. J. Burton Cleland in our correspondence columns last week[1] gave several examples of diseases and conditions which might reveal themselves to the sense of smell of the medical adviser. He instanced diabetes, enteric fever, acute rheumatism, plague, and retained placenta. The use of the nostrils in practical life is continually being more or less ignored. The mouth-breather forgets that originally the breath of life was breathed into man's nostrils; too often he breathes the breath of death through his mouth, for by the use of that channel he forfeits one of the protective mechanisms with which he has been endowed. Nostril breathers are able to detect at once if any putrescent nidus is in the vicinity and thereupon they will remove it or else themselves. It is notorious that the sense of smell (the "scent") of animals is often highly developed. It is stated that the odour emitted from a small-pox patient will attract cheetahs from afar; flies soon settle on decomposing matter, on tuberculous sputum, and, as was a common experience during the late South African campaign, over the heads of enteric fever patients. A peculiar smell with its associations is vividly recalled when perhaps years later it next reaches the olfactory area. Among other diseases than those above mentioned which can be diagnosed, with more or less certainty, by the sense of smell are abdominal fistula, bronchiectasis, cancers (undressed), some cases of erysipelas, favus (acetamide), some cases of fracture of the skull, gangrene of the lung, ozæna fœtida, hæmorrhoids (bleeding), pyæmia, septic mouth, stillicidium urinæ, and undressed varicose ulcers. The odours of excreta are sometimes a useful aid to diagnosis; thus tuberculous sputum smells like soaked bread. It has been noticed frequently that after conducting a post-mortem examination upon a highly odoured corpse the fæces of the operator will for about two days emit a similar stench. Drugs may reveal themselves in the breath or otherwise and thus give a clue to the malady for which they have been prescribed—thus alcohol, antimony, asafœtida, garlic, and iodoform. Similarly, a man who constantly when in public sucks a cachou or a mint-drop probably has very bad teeth and consequently foul breath. There is one caution which must be heeded—there may be an error in the observer's own nostrils; he may have lost his own sense of smell, as after an attack of influenza or having taken alcohol himself he may fancy he detects its odour in the breath of a person under examination. Finally, it would be useful to know if it is common for a smell to appear as an epileptic aura and if it ever happens that we smell in our dreams.

THE IMPERIAL CANCER RESEARCH FUND.

THE annual meeting of the Imperial Cancer Research Fund was held on July 25th at the Examination Hall of the Royal Colleges on the Embankment. Reports from the executive committee, the general superintendent, and the honorary treasurer were read. It was announced that the difficulty which had arisen with the Post Office concerning the transmission through the post of specimens of cancer had been satisfactorily cleared up in the month of March. The report of Dr. E. F. Bashford, the general superintendent, contained matters of great interest concerning the growth of cancer and the possibility of protecting mice from the consequences of experimental cancer. Dr. Bashford points out that the results of these experiments "only indicate the possibility of rendering normal mice unsuitable for the growth of experimental cancer. They have not enabled us to arrest the progress of experimental tumours, far less to effect the cure of the disease occurring naturally." It is well, we think, that the report should contain these words, for the members of the public at large are only too prone to catch at any straw which may appear to offer a chance of saving themselves from the abyss of cancer. We are beginning to see light on the problem but only a glimmer. We hope to treat the matter contained in the report at greater length in a future issue.

TREATMENT OF DIPHTHERITIC PARALYSIS WITH ANTITOXIN.

THE value of antitoxin in the treatment of diphtheria is now one of the best-established facts of therapeutics. But antitoxin does not appear to be used after the attack for the treatment of the most important sequel—the paralysis. At the meeting of the Société Médicale des Hôpitaux of Paris on June 15th M. J. Comby read an important paper on this use of antitoxin, to which we have previously referred.[1] He first published this treatment in July, 1904, and since that time a number of successful cases have been recorded by himself and other French writers. The following is an example. A man, aged 60 years, contracted a sore-throat for which only local treatment was used. Some days later he noticed a nasal intonation of the voice and regurgitation of fluid through the nose. These symptoms were only ephemeral, but some weeks later he had difficulty in walking and soon he became unable to leave his room. On examination atheromatous arteries, absent knee-jerks, and an aortic systolic murmur were found. Suspecting diphtheria, though entertaining the question of a vascular lesion of the nervous system, four injections, making a total of 80 cubic centimetres of antitoxin, were given in four days. Almost immediate improvement ensued and recovery took place in eight days. In another case a girl, aged 14 years, was admitted into hospital on March 24th last. On Jan. 14th she had a severe sore-throat, with formation of membrane, which was not treated with antitoxin. A short time afterwards the voice became nasal, liquid regurgitated through the nose, and there were strabismus and diplopia. These symptoms lasted only for a short time. A fortnight before admission she had difficulty in walking which increased until the lower limbs were completely paralysed. The upper limbs were affected in less degree. There was also paralysis of the trunk and neck; the child could not sit up in bed or lift the head. The knee-jerks were absent. In a great number of muscles both galvanic and faradic excitability was abolished. On March 25th and 26th two injections of 20 cubic centimetres of Roux's antitoxin were given, and on the 27th, 28th, and 29th three injections of ten cubic centimetres (70 cubic centimetres in all). On the second day of the treatment the patient easily moved her legs. At the end of the treatment she could sit up in bed. After a week recovery was complete except that the knee-jerks were still absent. M. Comby has treated nine cases of diphtheritic paralysis by this method and in all rapid recovery occurred. In most of the cases the paralysis was severe and took a generalised or an ascending form. Previously fatal cases of his cases of late diphtheritic paralysis were several. M. Comby drew the following conclusions. 1. Every case of diphtheritic paralysis, early or late, localised or generalised, should be treated with antitoxin. 2. The injections should be given on several days in succession in doses of from ten to 20 cubic centimetres, according to the age, so that a total quantity of 60 to 80 cubic centimetres of Roux's serum is given. 3. These injections are usually well tolerated and only exceptionally produce any symptoms. 4. Neither the age of the patient nor his previous state of health is a contra-indication. The injections should be given even when antitoxin has been administered in the stage of sore-throat.

THE COMPLICATIONS OF MUMPS.

AN interesting letter relating to the serious nature of the complications which may be associated with mumps in adults was published in THE LANCET of July 21st by Major F. Smith, R.A.M.C. In an outbreak of that disease among some troops under his charge Major Smith found that five cases out of a total of 11 had more or less serious complications, and he enters a noteworthy plea for the more serious consideration of that disease which is too often regarded as of a trivial character. Although mumps or epidemic parotitis is a highly contagious disease, yet the susceptibility to infection after exposure seems less general than in the case of many other specific contagious diseases; as a consequence, not a few escape infection in childhood, but epidemics from time to time occur in young adults, notably among soldiers or recruits. Several epidemics of this kind with a considerable proportion of serious complications or sequelæ have been recorded by French army surgeons. Moreover, second attacks of the disease, though rare, are by no means unknown and the attacks in these circumstances are often severe, according to Danchez.[1] The severe cases of mumps and those characterised by serious complications occur for the most part in those above the age of 12 years and particularly in adults. The list of complications and troublesome after-effects is a long and formidable one according to recent observations, and these are not necessarily associated with marked local conditions. Indeed, severe local complications are extremely rare. Suppuration in or about the gland is very uncommon and is then doubtless due to a secondary septic infection by way of the ducts of the glands; gangrene of the parotid gland is of even greater rarity. The facial paralysis which appears in some cases is probably due to compression of the facial nerve or to extension of the inflammatory process to its sheath, since it is a rule partial and temporary, recovering without special treatment in from six to ten days. It was observed seven times in 60 cases among young soldiers recorded by Courand and Petges.[2] Suppression of the salivary flow has also been observed to follow mumps.[3] Among the most serious complications are the so-called metastatic inflammations or metastases. These are doubtless due to the further spread and activity of the specific causative agent. The peculiarity of the special liability to infect the genital glands has long been known and orchitis is generally recognised as one of the most serious complications of the disease. It may occur without any parotid inflammation in rare cases and the possibility of this should be borne in mind during the course of an epidemic of the disease. It more usually occurs in the third or fourth week of the disease and lasts for a week or less, being not infrequently followed by rapid atrophy of the testicle affected by it. Comby found that this atrophy occurred in 103 instances among 163 cases of orchitis following mumps. Ovaritis, salpingitis, vulvo-vaginitis with œdema of the vulva, and mastitis occur in female cases, but more rarely. A singular difference between the incidence of the secondary inflammations in the two sexes is that whereas orchitis occurs almost invariably after the age of puberty, the ovaritis, vulvo-vaginitis, and mastitis may occur in young female children. It has been stated that pancreatitis may occur after mumps, and a case has been described[4] in which a boy developed pain in the abdomen on the fourth day with a tender swelling in the epigastrium. Lacrymal mumps has also been described by Hirschberg. Among the complications of the disease those affecting the nervous system demand special notice. High fever associated with delirium may occur in uncomplicated cases, probably from toxæmia, but occasionally signs of meningitis and even of involvement of the brain itself are observed and such signs have occurred in nearly all the fatal cases hitherto recorded. Peripheral neuritis has also been occasionally observed to follow the disease. Major Smith observed marked weakness of the lower limbs in several of his cases. Acute mania was observed in association with the disease by Dr. R. Percy Smith.[5] Of affections of the special senses, one of the most common and serious is deafness which may be due to otitis from spread of inflammation to the middle ear by the Eustachian tube, when it is usually recovered from, or to an actual incurable nerve deafness from affection of the labyrinth or of the nucleus of the auditory nerve. This condition may occur in the second week and may be preceded by tinnitus, vertigo, vomiting, and fever. Optic neuritis followed by atrophy has also been described but it is a sequel of extreme rarity. Other conditions described as occurring in association with mumps are endocarditis, pericarditis, arthritis, nephritis with uræmia, albuminuria, epistaxis, pneumonia, digestive disturbances with jaundice, enlargement of the spleen, and certain skin eruptions. The mildness of the typical disease as it occurs in children and the rapidity with which convalescence follows in uncomplicated cases have served to distract attention from the severe character of some of the associated conditions, and since many of these are more likely to occur after neglect or exposure during the course of the disease it is obviously of great importance that even in mild cases, especially in adults, the utmost care should be taken to treat them seriously and from the first appearance of the symptoms. Major Smith's interesting letter serves a useful purpose in emphasising the importance of the recognition of the serious character of the disease.

THE EMPLOYMENT OF A SPECIAL PATHOLOGIST BY A CORONER.

THE report of the district auditor (Mr. T. Barclay Cockerton) on the accounts of the London County Council for the year 1904–05 was circulated on Monday. The report says: "In the course of the audit the British Medical Association, represented by their counsel, together with other itepayers, appeared before me to object to the allowance of ertain disbursements by Mr. John Troutbeck, one of the oroners of the county. I carefully considered the objections nd on the 11th of January gave my decision that all the ayments objected to were legal and that the Council were ustified in charging them in these accounts. I have been sked to give a statement of my reasons for allowing he payments objected to, which reasons I have duly ntered in the book of account, according to the tatutory requirements. In giving my decision in favour f the Council I expressed my sympathy with the members f the medical profession who were affected by the mode f procedure adopted by Mr. Troutbeck. At the same time I desire to take this opportunity of saying that I am convinced that both the public control committee of the Council nd the coroner have been solely influenced by a desire to scertain effectually the cause of death in cases where nquests are held and to act generally in the public interest. I may say, however, that in my opinion the Coroners Act of 1887, on which the objectors relied, never contemplated the employment of a special pathologist in the manner adopted by Mr. Troutbeck. I would therefore strongly urge the passing of an amending Act in order to remove some of the difficulties in connexion with this matter and I understand that the Council have for the past 11 years been endeavouring to obtain an amendment of the law in this direction." The finance committee of the *London County Council*, to whom the auditor's report was referred, states that the matter in question is receiving consideration

PROMOTION OF AGRICULTURAL RESEARCH.

AN interesting letter written by Professor H. E. Armstrong, F.R.S., has recently been published in the *Times* on this subject, from which it would appear that there is a limit to the useful application of artificial manures or, to use a better term, fertilisers. We can quite believe it, and that these essential aids to agriculture are misused has long been our opinion. It should be remembered that a soil can be just as easily made sick of a special manure as of a special crop. In other words, we consider that the old plan of rotations should not be overlooked in dealing with the cultivation of experimental plots and that continually to grow the same crop year after year, no matter how careful the manuring, is flagrantly to violate the laws of nature and to court a breakdown. There should also be more analyses of the soil; the various so-called non-essential ingredients may be wanting and may suddenly assume vital importance One reason why manures sometimes fail in the hands of the ordinary farmer is that they are applied with most callous indifference to the state and the requirements of the soil. The golden rule is to supply the deficiency. The ordinary farmer should first see if the soil is properly limed; the simple test—effervescence with hydrochloric acid—as suggested by Dr. B. Dyer, who has done so much for scientific agriculture, should be tried. Superphosphate is acid and should not be applied to an acid soil. Hundreds of pounds are spent on improvements on farms, yet how few farmers can tell the reaction of their soil and its simple analysis. Manure is dumped where it can do nothing but outrage nature, and of all dumping the dumping of artificial manure is the worst It is desirable, we think, that manufacturers should state the reaction to, say, methyl orange clearly in their invoices This omission of stating the acidity has been much against them, as it has led to improper use of fertilisers. To receive an acid manure properly the soil must be alkaline; this is the keynote to successful application. The invent[illegible] of the late Sir John Lawes was of the most valuable kin[illegible] agriculture. The Government should surely take over, amplify, and extend its experiments, which thus strengthened would confer fresh benefits not only on England but on the whole human race.

THE FACTORY GIRLS' COUNTRY HOLIDAY FUND.

WE have received an appeal on behalf of this fund signed by, amongst others, the Duke of Norfolk, the Bishop of Southwark, the Bishop of Stepney, Dr. Adler the Chief Rabbi, Canon Scott Holland, and the Rev. Dr. R. F. Horton. These names alone are sufficient to show the non-sectarian nature of the fund while we have on many occasions pointed out the wisdom of providing for poor factory girls a holiday in the country. From whatever standpoint we may view this fund, be it that of charity, public health, or the future well-being of the race, there can be but one conclusion—namely, that it is well deserving of support. Already 5000 applications have been received from work-girls or those representing them and 1500 of these have been dealt with. The organisers of the fund as far as possible require the applicants to help themselves and they do so by saving up their pence week by week. In this way they provide on an average about a quarter of the sum required; last year their contributions amounted to £1200. The committee points out that these girls and women work for long hours day after day, live in small and crowded tenements, and earn for the most part from 4*s.* to 12*s.* a week. The holiday is looked forward to by them for months in advance; *it is looked back upon and talked about for months* afterwards It often happens that a girl who has herself enjoyed the benefit of a holiday in former years in her anxiety to get a holiday for a sister or a friend is prepared to sacrifice her own, for, as her people say, she comes back looking and feeling quite a different being, built up, and ready to resume cheerfully her work and troubles until holiday time comes round once more. The committee has received 1000 more applications than usual and it is reluctantly compelled to refuse fresh ones until those already sent in have been dealt with. Subscriptions should be sent to the honorary secretary, St. Peter's Rectory, Saffron-hill, London, E C.

THE ADMISSION OF CASES OF TYPHOID FEVER INTO GENERAL HOSPITALS.

FROM time to time the question of the admission of cases of typhoid fever into the wards of general hospitals comes up for discussion. The tendency has been to treat cases of specific infectious disease in isolation hospitals and many cases of typhoid fever have been transferred to such institutions for treatment. In most, if not all, of the large general hospitals in London, however, cases of that disease are admitted, sometimes into special wards but more frequently into the general wards. Since the infective agent causing the disease is known and the modes of infection are now generally recognised, there can be little doubt that given satisfactory sanitary arrangements and skilled nursing there is no danger of the spread of the disease by such admissions and from many points of view it would be a matter for regret if cases of typhoid fever were excluded from general hospitals. It is eminently desirable that both medical practitioners and nurses should be familiar with the disease, its treatment, and the prophylactic measures necessary to prevent its spread, and for this purpose a closer association with actual cases is necessary than is likely to be obtained by the ordinary course of instruction at special hospitals.

THE Department of Public Health of Queensland states, in a bulletin dated June 16th for the week ending that day, that a mild case of bubonic plague occurred on June 9th. The patient was a male employed as a porter at Roma-street railway-station, Brisbane, and at the date of the bulletin was convalescent. As regards Hong-Kong, a telegram from the Governor received at the Colonial Office on July 23rd states that for the week ending July 21st there were 7 cases of plague and 5 deaths from the disease.

THE death is announced, at the age of 69 years, of our eminent French *confrère*, Dr. Brouardel, who has for many years been professor of legal medicine at the University of Paris. Dr. Brouardel was also an authority upon practical hygiene and a prolific medical author. We hope to give some details of his life and work in an early issue.

THE annual dinner of the old students of St. Thomas's Hospital will take place on Tuesday, Oct. 2nd, at the Hotel Cecil, London, at 7 for 7.30 P.M. Dr. Arthur Newsholme, medical officer of health of Brighton, will be in the chair.

THE death occurred on Friday last of Mr. E. Noble Smith, senior surgeon to the City Orthopædic Hospital and author of a well-known work upon orthopædic surgery.

Mr. Charles Alfred Ballance, M.B., M.S. Lond., F.R.C.S. Eng., has been appointed a member of the Royal Victorian Order of the Fourth Class.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

NEW HISTORICAL SUMMARY.

THE recently prepared Historical Summary of the Royal College of Surgeons is of special interest as being the first account of the corporate life of the College. It is worthy of note that the College centenary in 1900 led many to think that the College of Surgeons as an institution was only 100 years old, whereas the corporate lineage of the College could be traced back for nearly six centuries. The summary, of which the following is an extract, has been prepared by the ex-President, Mr. John Tweedy, F.R.C.S., and Mr. S. Forrest Cowell, the secretary.

The early history of the Royal College of Surgeons of England is the history of two companies which, existing at first as separate fraternities or guilds, were for a time united into one body corporate, and finally became resolved again into two distinct corporations. One of these, the Barbers' Company of London, is first definitely mentioned in the records preserved at the Guildhall in the year 1308, when Richard le Barber was presented and sworn before the court of aldermen as Master and Supervisor of the Barbers' Guild; and from an ordinance of the City made in the previous year it is evident that the barbers of London were at that time engaged in the practice of at least some branches of surgery. The other company, known as the Fellowship or Guild of Surgeons, is mentioned in the City records in the year 1369.

Between these two bodies there was for many years a keen rivalry and jealousy. Each tried by turns to attain supremacy of authority and jurisdiction in matters relating to the practice of surgery. In the year 1376 the barbers made a complaint to the mayor and aldermen against unskilled practitioners in surgery, and obtained an ordinance providing that two masters should be appointed annually to direct and rule the craft, to inspect instruments, and to see that none should be admitted to the franchise of the City except after attestation of their skill by good examination. 14 years later, however, four masters of the surgeons' guild were sworn before the court of aldermen and they were invested with the power of scrutiny among persons practising surgery and with authority to present defaults. But in the year 1410 the barbers obtained from the court of aldermen confirmation of the privileges granted to them in 1376 with the addition that they should be enjoyed "without the scrutiny of any person or persons of any other craft or trade under any name whatsoever other than the craft or trade of the said Barbers."

The Barbers' Company was by this time assuming a two-fold character, for it consisted of two classes of members—those who were barbers simply or practised only the minor branches of surgery, such as blood-letting and tooth-drawing, and those who exercised the faculty of surgery. In the year 1415 the mayor and aldermen required the company to furnish them with a list of all the latter class of members, from which they selected two as masters of those practising surgery, leaving to the company itself the election of the masters of the barbers. Meanwhile the Guild of Surgeons sought an alliance with the physicians. About the year 1423 they obtained an ordinance from the court of aldermen having for its object an association or commonalty of physicians and surgeons. Fortified by the support of the physicians the surgeons once more challenged the surgical privileges of the barbers but these were again confirmed by the mayor and aldermen in 1424. The scheme for a combination of physicians and surgeons fell through but the surgeons continued a separate body with ordinances for the government of their Society.

Freed from opposition the Barbers' Company continued to grow in importance and in the year 1462 the right of its members to practise surgery was definitely established by Letters Patent granted by Edward IV. in the first year of his reign. This charter, from which the Royal College of Surgeons of England, as recited in the charter of 1800, dates its constitutional history as a body corporate, was granted to the freemen of the mystery of barbers of the City of London practising surgery. They were made one body and perpetual community with a common seal and with power to hold lands and to make by-laws.

In the year 1493 the Guild of Surgeons, which had continued as a separate body, entered into an alliance or "composition" with the Barbers' Company, by which the two companies agreed each to appoint two wardens, the four so appointed to act together in all matters relating to surgery and to the examination and government of its practitioners. The charter granted by Edward IV. to the Barbers' Company was confirmed by Henry VII. and also by Henry VIII., but in 1511 an Act (3 Henry VIII., cap. 11) was passed, constituting a further licensing authority by enacting that no person should practise as a physician or surgeon in London, or within seven miles of the same, unless first examined and approved by the Bishop of London, or the Dean of St. Paul's, with the assistance of four physicians or surgeons. In the year 1540 the two companies were formally united by Act of Parliament. The Act (32 Henry VIII., cap. 42), after reciting that there were two distinct companies of surgeons in London, one called the Barbers of London and the other the Surgeons of London, enacted that the two companies should from thenceforth be united and made one body corporate to be called by the name of the Masters or Governors of the Mystery of the Commonalty of the Barbers and Surgeons of London. The united company was to enjoy all the rights and privileges at any time granted to the two separate companies. Four masters, two to be surgeons and two to be barbers, were to be appointed annually; barbers were forbidden to perform any surgical operations except the drawing of teeth and surgeons were not to exercise the craft of barbery and shaving. Provision was also made for the study of anatomy by giving the company the right to claim four bodies annually of persons executed for felony. Thomas Vicary, Serjeant-Surgeon to Henry VIII. and afterwards to Mary and to Elizabeth, was elected the first master. The united company shared the possession of Barbers' Hall, which is known to have occupied its present site in Monkwell-street since 1490, and was probably there even before that. The hall, subsequently added to by Inigo Jones in 1636, is still standing, having escaped destruction in the Great Fire of London.

The union thus effected was destined to last for more than 200 years. At first, however, the privileges conferred on the surgeons of the company appear to have excited opposition, for in the thirty-fourth and thirty-fifth years of Henry VIII. an Act was passed allowing unlicensed persons to treat outward sores and swellings with herbs and ointments.

During the reign of Queen Mary, in the year 1555, regulations were drawn up relating to the examination of persons for the company's licence to practise. These regulations provided for the appointment of 13 examiners, including the master and two governors. This is the origin of the present court of examiners of the Royal College of Surgeons.

In the year 1605 the company obtained a charter from James I. providing that the governing body of the company should consist of four masters, two of whom were to be

railway-station, Brisbane, and at the date of the bulletin was convalescent. As regards Hong-Kong, a telegram from the Governor received at the Colonial Office on July 23rd states that for the week ending July 21st there were 7 cases of plague and 5 deaths from the disease.

THE death is announced, at the age of 69 years, of our eminent French *confrère*, Dr. Brouardel, who has for many years been professor of legal medicine at the University of Paris. Dr. Brouardel was also an authority upon practical hygiene and a prolific medical author. We hope to give some details of his life and work in an early issue.

THE annual dinner of the old students of St. Thomas's Hospital will take place on Tuesday, Oct. 2nd, at the Hotel Cecil, London, at 7 for 7.30 P.M. Dr. Arthur Newsholme, medical officer of health of Brighton, will be in the chair.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

NEW HISTORICAL SUMMARY.

THE recently prepared Historical Summary of the Royal College of Surgeons is of special interest as being the first account of the corporate life of the College. It is worthy of note that the College centenary in 1900 led many to think that the College of Surgeons as an institution was only 100 years old, whereas the corporate lineage of the College could be traced back for nearly six centuries. The summary, of which the following is an extract, has been prepared by the ex-President, Mr. John Tweedy, F.R.C.S., and Mr. S. Forrest Cowell, the secretary.

The early history of the Royal College of Surgeons of England is the history of two companies which, existing at first as separate fraternities or guilds, were for a time united into one body corporate, and finally became resolved again into two distinct corporations. One of these, the Barbers' Company of London, is first definitely mentioned in the records preserved at the Guildhall in the year 1308, when Richard le Barber was presented and sworn before the court of aldermen as Master and Supervisor of the Barbers' Guild; and from an ordinance of the City made in the previous year it is evident that the barbers of London were at that time engaged in the practice of at least some branches of surgery. The other company, known as the Fellowship or Guild of Surgeons, is mentioned in the City records in the year 1369.

Between these two bodies there was for many years a keen rivalry and jealousy. Each tried by turns to attain supremacy of authority and jurisdiction in matters relating to the practice of surgery. In the year 1376 the barbers made a complaint to the mayor and aldermen against unskilled practitioners in surgery, and obtained an ordinance providing that two masters should be appointed annually to direct and rule the craft, to inspect instruments, and to see that none should be admitted to the franchise of the City except after attestation of their skill by good examination. 14 years later, however, four masters of the surgeons' guild were sworn before the court of aldermen and they were invested with the power of scrutiny among persons practising surgery and with authority to present defaults. But in the year 1410 the barbers obtained from the court of aldermen confirmation of the privileges granted to them in 1376 with the addition that they should be enjoyed "without the scrutiny of any person or persons of any other craft or trade under any name whatsoever other than the craft or trade of the said Barbers."

The Barbers' Company was by this time assuming a two-fold character, for it consisted of two classes of members—those who were barbers simply or practised only the minor branches of surgery, such as blood-letting and tooth-drawing, and those who exercised the faculty of surgery. In the year 1415 the mayor and aldermen required the company to furnish them with a list of all the latter class of members, from which they selected two as masters of those practising surgery, leaving to the company itself the election of the masters of the barbers. Meanwhile the Guild of Surgeons sought an alliance with the physicians. About the year 1423 they obtained an ordinance from the court of aldermen having for its object an association or commonalty of physicians and surgeons. Fortified by the support of the physicians the surgeons once more challenged the surgical privileges of the barbers but these were again confirmed by the mayor and aldermen in 1424. The scheme for a combination of physicians and surgeons fell through but the surgeons continued a separate body with ordinances for the government of their Society.

Freed from opposition the Barbers' Company continued to grow in importance and in the year 1462 the right of its members to practise surgery was definitely established by Letters Patent granted by Edward IV. in the first year of his reign. This charter, from which the Royal College of Surgeons of England, as recited in the charter of 1800, dates its constitutional history as a body corporate, was granted to the freemen of the mystery of barbers of the City of London practising surgery. They were made one body and perpetual community with a common seal and with power to hold lands and to make by-laws.

In the year 1493 the Guild of Surgeons, which had continued as a separate body, entered into an alliance or "composition" with the Barbers' Company, by which the two companies agreed each to appoint two wardens, the four so appointed to act together in all matters relating to surgery and to the examination and government of its practitioners. The charter granted by Edward IV. to the Barbers' Company was confirmed by Henry VII. and also by Henry VIII., but in 1511 an Act (3 Henry VIII., cap. 11) was passed, constituting a further licensing authority by enacting that no person should practise as a physician or surgeon in London, or within seven miles of the same, unless first examined and approved by the Bishop of London, or the Dean of St. Paul's, with the assistance of four physicians or surgeons. In the year 1540 the two companies were formally united by Act of Parliament. The Act (32 Henry VIII., cap. 42), after reciting that there were two distinct companies of surgeons in London, one called the Barbers of London and the other the Surgeons of London, enacted that the two companies should from thenceforth be united and made one body corporate to be called by the name of the Masters or Governors of the Mystery of the Commonalty of the Barbers and Surgeons of London. The united company was to enjoy all the rights and privileges at any time granted to the two separate companies. Four masters, two to be surgeons and two to be barbers, were to be appointed annually; barbers were forbidden to perform any surgical operations except the drawing of teeth and surgeons were not to exercise the craft of barbery and shaving. Provision was also made for the study of anatomy by giving the company the right to claim four bodies annually of persons executed for felony. Thomas Vicary, Serjeant-Surgeon to Henry VIII. and afterwards to Mary and to Elizabeth, was elected the first master. The united company shared the possession of Barbers' Hall, which is known to have occupied its present site in Monkwell-street since 1490, and was probably there even before that. The hall, subsequently added to by Inigo Jones in 1636, is still standing, having escaped destruction in the Great Fire of London.

The union thus effected was destined to last for more than 200 years. At first, however, the privileges conferred on the surgeons of the company appear to have excited opposition, for in the thirty-fourth and thirty-fifth years of Henry VIII. an Act was passed allowing unlicensed persons to treat outward sores and swellings with herbs and ointments.

During the reign of Queen Mary, in the year 1555, regulations were drawn up relating to the examination of persons for the company's licence to practise. These regulations provided for the appointment of 13 examiners, including the master and two governors. This is the origin of the present court of examiners of the Royal College of Surgeons.

In the year 1605 the company obtained a charter from James I. providing that the governing body of the company should consist of four masters, two of whom were to be

36 bronze medals, was announced by Mr. H. D. Searle-Wood, chairman of the committee of judges, which included Dr. Philip Boobbyer, Colonel J. Lane Notter, R.A.M.C. (retired), Dr. Louis C. Parkes, and Dr. George Reid.

The exhibits were divided into sections dealing with all branches of sanitation. In Division A (Science in Relation to Hygiene) Mr. George Blissett, 71, Brookwood-road, Southfields, London, S.W., exhibited a wide range of optical instruments and appliances, including a collection of ancient spectacles and spectacles for ordinary and special purposes. Mr. Joseph W. Lovibond, The Laboratories, Salisbury, showed apparatus for establishing the colours of healthy and abnormal bloods and for showing their deviation by a system of curves. An apparatus for measuring the colour of potable and contaminated water and effluents also attracted attention. In Division B (Hygiene of Special Classes, Trades, and Professions) Messrs. Wilson and Stockall, Bury, Lancashire, gave prominence to ambulance vehicles, including a patent brougham ambulance, fitted with a stretcher and two seats, one for a sitting patient, the other for an attendant, and specially designed for easy disinfection. They also showed a motor ambulance, mounted on a 12–14 h.p. chassis, containing two stretchers, one above the other, and two seats for attendants. The compactness of the design enables the vehicle to be used in the narrow streets of large towns. Messrs. Pocock Brothers, 235, Southwark Bridge-road, London, S.E., gained a silver medal for a completely equipped indiarubber padded room, of full size, fitted with a drainage gully and all known modern appliances. A large number of excellent coloured charts, designed for the teaching of young children, by Messrs. E. J. Arnold and Son, Limited, publishers, Butterley-street, Hunslet-lane, Leeds, gained considerable notice. For example, a set of eight charts on physiology dealt with the elementary principles of physiology, hygiene, and first aid; a large chart gave practical hints on fresh air and light, food and drink, warmth and clothing, bathing, rest and exercise, and various household matters; while another chart indicated the best and safest things to do in an emergency in cases of simple injuries and ailments. The exhibit of Messrs. Monat and Company, 8, St. Paul-street, Portland-square, Bristol, consisted of a safety mail-cart for children, so designed that when the attendant's hands are removed from the shafts a brake is automatically set in action. The cart was fitted in addition with a novel safety belt for securing a child while allowing it sufficient freedom of movement.

In Division C (Construction and Sanitary Apparatus) reference may be made to the sewage distributors of Mr. George Percival Milnes, 6, Rowcroft, Stroud, Gloucestershire; Messrs. H. Birch, Killon, and Co., 20, Cooper street, Manchester; and Messrs. W. Harriman and Co., Limited, 1, Charlotte-square, Newcastle-on-Tyne. Improved hospital lavatories were shown by Mr. John Jones, Carlyle Works, Chelsea, S.W.; Messrs. Doulton and Co., Albert Embankment, London, S.E.; and Messrs. Shanks and Co., Limited, Barrhead, Glasgow. Messrs. George Howson and Sons, Limited, Hanley, Staffs, included types of lavatories suitable for use in operating theatres, with a lever apparatus to operate the taps and a knee lever to operate the waste. Other forms of operating theatre lavatories were shown by Messrs. Doulton and Co., together with a fireclay mortuary slab and an oblong sink for operating rooms, fitted with an aseptic filter and irrigators, and a mixing valve for hot and cold water over the sink, with spray and jet nozzles. Messrs. Pountney and Co., Limited, Fishponds, Bristol, made a feature of semi-porcelain lavatory basins that will not craze, a point of importance in hospital fittings. Much interest was taken in the appliances for the prevention of smoke, of which the exhibit of the British Fuel Economiser and Smoke Preventer Co., 9, Bedford-row, London, W.C., was prominent. Ozonair, Limited, 27, Chancery-lane, London, W.C., showed in operation types of apparatus for the commercial production of ozone which is claimed to be free from oxides of nitrogen. The B.V. type is intended for purifying the atmosphere in hospitals and other buildings and the P.M. type is designed for medical use in the treatment of diseases of the skin and other complaints. Other types are made for the bleaching of foods—e.g., treacle, sugar, and flour, also fabrics, and for the maturing of tobacco and whisky. The makers of the apparatus claim that it is possible in an hour to mature whisky by means of ozone to the same extent as is usually attained by years of storage. One of the most novel exhibits was a window fitted with a collapsible ventilator for producing efficient ventilation without draught exhibited by the Combination Collapsible Ventilator Co., 85, Duke-street, Liverpool. Among the numerous stoves on view was the D. O. Boyd's "Hygiastic" Warm Air Ventilating Grate, made by Messrs. Hendry and Pattisson, Lavender hill, London, S.W.; it was tested on behalf of the Smoke Abatement Society and lettered A in the report on Test of Certain Open Domestic Grates published in THE LANCET of May 19th, p. 1413. Mr. E. G. Wright, 44, Woodbridge road, Guildford, Surrey, showed a hot-air system for bringing warm air into rooms in winter and cold air in summer without producing draughts.

In Division D (Personal and Domestic Hygiene) Messrs. J. S. Fry and Sons, Limited, Union-street, Bristol, exhibited their malted cocoa, a combination of Fry's pure cocoa extract with Allen and Hanbury's extract of malt. Messrs. Cadbury Bros., Limited, Bourneville, near Birmingham, exhibited their well-known cocoas.

QUACKS AND ABORTIFACIENTS.

AT the recent Nottingham Assizes, before Mr. Justice Walton and a jury, the case of Rex v. Seagrave (*alias* Wardle), where the accused was charged with the sale of diachylon as an abortifacient, resulted in a conviction of the prisoner in circumstances that will be of interest to our readers.

The attention of the medical profession in and around Nottingham has been directed for some time to the increasing use of diachylon as an abortifacient among the working classes. Since the passing of the Midwives Act, moreover, inquiries have been systematically made in the city of Nottingham with regard to cases of still-birth and abortion notified to the local authority under the Act, and in many instances there has been a strong suspicion that lead pills had been taken for the purpose of procuring abortion. Special attention was given to Bulwell, an outlying part of Nottingham, as the reports received from that place showed that the practice was very common there. Cases of lead poisoning, exclusively confined to women of child-bearing age, were stated to be of continual occurrence in this suburb. The pills used in Bulwell were commonly spoken of as "Mrs. Seagrave's pills" and this Mrs. Seagrave (*alias* Wardle) was said to do quite an extensive trade in them, selling them to both married and unmarried women. About ten recent cases were cited in which there was a definite history of lead poisoning and abortion and the corporation authorities considered that an attempt should be made to obtain some of the pills for analysis, so that if possible legal proceedings might be taken against Mrs. Wardle. A box of pills was procured by an agent of the health department and these were found on analysis to consist of diachylon (from 50 to 70 per cent.) and aloes, with an outer coating of boric acid. They were roughly made and varied in size from one and a half grains to five grains. The case was now handed over to the police who arrested Mrs. Wardle and searched her house, where a large quantity of pills similar in composition to those which had been analysed were found and also the implements and materials used in making them. The prisoner was brought before the magistrate and three witnesses were produced who had bought pills from her and had been seriously ill after taking them. Medical evidence was adduced to show that in each case these women had aborted and had suffered from lead poisoning. On the evidence given the magistrates committed the prisoner to the assizes, the defence being reserved.

The case was heard at the Nottingham Assizes on July 17th and 18th, the prisoner being indicted on four charges of supplying pills "containing a certain poison called lead, with intent to procure abortion." As before, the prosecution called witnesses to prove the purchase of the pills from Mrs. Wardle and the ill effects produced by taking them. The medical men who had attended these witnesses again gave evidence that lead poisoning and abortion had occurred in each case. The city analyst described the result of his analysis of the pills and the medical officer of health corroborated this and also spoke at length as to the serious results that would follow the taking of such pills for any considerable period. The women who had purchased pills all stated that Mrs. Wardle had instructed them to take a dose of Epsom but they have not been successful as a rule unless gross negligence was proved. It may perhaps be of some interest to refer to a few. In Lanphier *v.* Phipos (8 Car. & P. 475) it was said that every person who enters into a learned profession undertakes to bring to the exercise of it a reasonable degree of care and skill; he does not, if he is an attorney, undertake at all events to gain the cause; nor does a surgeon undertake that he will perform a cure; nor does the latter undertake to use the highest possible degree of skill, as there may be persons of higher education and greater advantages than himself, but he undertakes to bring a fair, reasonable, and competent degree of skill; and in an action against him by a patient the question for the jury is whether the injury complained of must be referred to the want of a proper degree of skill and care in the defendant or not. In Pimm *v.* Roper (2 F. & F. 783) a surgeon having been employed by a railway company to examine a passenger who had sustained an injury in a collision on their line, and the surgeon having so far as he could see or judge, on the plaintiff's own statement of his injuries, told him that they were so slight that he (the plaintiff) accepted a small sum in compensation, it was held, even assuming that his injuries were greater, there was no ground of action. In an action by a person who had been a patient at a hospital for maltreatment there by two of the surgeons, it appeared that the alleged maltreatment was in the administration of a hot bath which they had ordered, but which it was no part of their ordinary duty personally to direct and to superintend and at the actual administration of which they were not present, it was held in Perionowsky *v.* Freeman (4 F. & F. 977) that the plaintiff was not entitled to expect more than the usual and ordinary degree of care and attention at the hands of the surgeons and that if they were not personally cognisant of the alleged ill-usage they were not liable. To render a medical man liable for negligence or want of due care or skill it is not enough that there has been a less degree of skill than some other medical man might have shown or a less degree of care than even he himself might have bestowed, nor is it enough that he himself acknowledged some degree of want of care; there must have been a want of competent and ordinary care and skill and to such a degree as to have led to a bad result (Rich *v.* Pierpont, 3 F. & F. 35). But every medical practitioner who by a culpable want of attention and care or by the absence of a competent degree of skill and knowledge causes injury to a patient is liable to a civil action for damages unless such injury be the immediate result of intervening negligence on the part of the patient himself or unless such patient has, by his own carelessness, directly conduced to such injury. In Slater *v.* Baker and Stapleton (2 Wils. 359) the plaintiff employed the defendants, the first-named being a surgeon and the second an apothecary, to cure his leg, which had been broken and set, and the callus of the fracture formed. The defendants *disunited the callus* and Baker fixed on to the plaintiff's leg a heavy steel instrument with teeth to stretch or to lengthen the leg. In a special action upon the case against the defendants the plaintiff recovered £500 damages against them jointly; and in answer to an objection that the action ought to have been trespass *vi et armis* for breaking the plaintiff's leg without his consent the court replied: "It appears from the evidence of the surgeons that it was improper to disunite the callus without consent. This is the usage and law of surgeons. Then it was ignorance and unskilfulness in that very particular to do, contrary to the rule of the profession, what no surgeon ought to have done; and, indeed, it is reasonable that a patient should be told what is about to be done to him, that he may take courage and put himself in such a situation as to enable him to undergo the operation. For anything that appears to the court, this was the first experiment made with this new instrument; and if it was, it was a rash action, and he who acts rashly acts ignorantly; and although the defendants, in general, may be as skilful in their respective professions as any two gentlemen in England, yet the court cannot help saying that, in this particular case, they acted ignorantly and unskilfully, contrary to the known rule and usage of surgeons." A medical man is liable to a civil action for injury resulting to a patient from his negligence or unskilful treatment, although the patient neither employed nor was to pay him. Thus in Longmeid *v.* Holliday (6 Exch. 767), Baron Parke said: "If an apothecary administers improper medicines to his patient, or a surgeon unskilfully treats him, and thereby injures his health, he will be liable to the patient, even where the father or friend of the patient may have been the contracting party with the apothecary or surgeon; for, though no such contract had been made, the apothecary, if he gave improper medicines, or the surgeon, if he took him as a patient and unskilfully treated him, would be liable to an action for a misfeasance"; and in Pappin *v.* Sheppard (5 Bing. N. C. 733), which was an action by a man and his wife against a surgeon for an injury to the wife by reason of the defendant's improper and unskilful treatment, Chief Baron Richards said: "From the necessity of the thing the only person who can properly sustain an action for damages for an injury done to the person of a patient is the patient himself, for damages could not be given on that account to any other person, although the surgeon may have been retained and employed by him to undertake the cure"; and in the same case Baron Garrow said: "In cases of the most brutal inattention and neglect the patients would be precluded frequently from seeking damages by course of law, if it were necessary to enable them to recover that there should have been a previous retainer on their part of the person professing to be able to cure them. In all cases of surgeons retained by any of the public establishments it would happen that the patient would be without redress, for it could hardly be expected that the governors of an infirmary should bring an action against the surgeon employed by them to attend the child of poor parents who may have suffered from his negligence and inattention."

Boric Acid added as a Preservative to Potted Meats.

A firm of provision merchants holding large contracts for the supply of provisions to army canteens was summoned recently at the Brentford police-court under the Sale of Food and Drugs Act for selling certain tinned meats which were not of the nature and quality of the articles demanded. The articles in respect of which the summons was taken out consisted of chicken and tongue, chicken and ham, and ham contained in tins the price of which was 1*d.* each and the adulteration complained of consisted of the addition of boric acid as a preservative in a proportion equivalent to 52 grains of borax per pound. There was also evidence that colouring matter in the form of oxide of iron had been used. After a considerable amount of expert evidence had been given on both sides the bench held unanimously that there must be a conviction on the ground that the article sold was rendered injurious by the addition of boric acid in the proportion proved, pointing out that it had been admitted by a witness called for the defence that the preservative might injure a child or a person not in robust health, although it might have no effect upon a healthy adult. A fine of £5, with 50 guineas costs, was imposed. In this case the evidence of the prosecution was not directed to showing any general or certain danger arising out of the presence of boric acid but was confined to the points that in the case of sound meats preserved by being "tinned" it was quite unnecessary and that its effect might be prejudicial to the consumer according to the amount consumed and other circumstances. It was also pointed out that although it was not suggested that the meat forming the subject matter of the prosecution was unsound, and although boric acid would not act as a deodoriser, the preservative might act so as to arrest incipient decomposition without averting the effects of that which had already taken place and also that the summons was not taken out in respect of potted meat which would be kept after the tin was opened but in respect of small tins costing a penny each which would be consumed at once. The suggestion put to a witness that borax might be used medicinally was met with the natural answer that this would not make it desirable to administer it indiscriminately in food. The evidence called for the defence was to the effect that borax was generally used as a preservative, particularly in the case of ham, which it was suggested was due to the modern demand for hams "mildly" cured and was more particularly called for the purpose of establishing the general want of proof of ill-effects arising from its use. The conclusion to which the case points would seem to be that the use of boric acid as a preservative should be discouraged in every possible manner, not on account of any serious danger necessarily arising in all cases where it is employed, but on account of the difficulty of allowing its use in moderation and of, at the same time, detecting and punishing its abuse when added in excessive quantities and for an illicit object.

order to prevent the spread of infection she nevertheless disregarded the notice and attended a confinement as a midwife.

The Board directed the name of this midwife to be removed from the roll.

THE AUSTRIAN EXHIBITION AT EARL'S COURT.

SOME years have elapsed since there has been so serious an exhibition at Earl's Court. There was a danger that these annual exhibitions would degenerate into mere out-of-door entertainments, where bands, the Big Wheel, the water-chutes, the gardens, and various side shows would constitute the chief attractions. This year, however, we have, for the first time, an Austrian exhibition and both public bodies and private enterprise of that country have really endeavoured worthily to be represented. As a result the exhibition constitutes quite an object lesson in regard to the resources of the empire. The heavier industries—coal mining, ironworks, leather dressing, cotton and wool, &c.—are, it is true, scarcely represented. It is mainly the Austria of the tourist that we see; and this includes those who travel not merely for pleasure but for health. There is, indeed, quite an important section devoted to the great Austrian balneological stations This will be found on the right-hand side of the Royal Galleries if entered from the Brompton or the Tyrolese Village side, close to the colonnade that surrounds the oval known as the Royal Galleries, in a quiet inner compartment. Here these exhibits can be studied at ease. At one end there is an oil painting of Abbazia. It shows the beautiful position occupied by this celebrated resort of the Adriatic Riviera. Close at hand, on a large stand, an extensive display of bottles and pamphlets are intended to convey some idea of the benefits to be derived from the arsenious iron baths of Levico-Vetriolo. These are valleys 1600 feet and 3000 feet respectively above the level of the sea and situated near Trent in the South Tyrol. The railway journey from London takes 38 hours and the spring and autumn are the favourite seasons. The waters are rich in proto-sulphate of iron and of arsenious acid, and there is also a summer bathing establishment, for the waters are used externally and internally.

The advantage and it is a very great advantage, of this section of the exhibition is that every detail of needful information can be obtained concerning the various health resorts. For instance, in regard to most resorts we can ascertain not only the composition of the waters and the diseases for which they are employed but the charges made for the baths, the different forms of treatment, and for the Kurtax, and what sports, concerts, and entertainments are provided in return for this tax. Here, likewise, a large number of photographs can be seen. There is notably a very fine photograph of Meran, while albums provide views of the details of the baths and their organisation. There are statistics also, and thus we learn, for instance, that 30,000 visitors annually frequent the sulphur baths of Baden, near Vienna. But in autumn this method of treatment may be varied with "the grape cure," which agreeable *régime* doubtless attracts many persons. Then the hotels are organised so that the food of the residents may be in accordance with the directions laid down by the medical attendants.

Close at hand are the exhibits of the Teplitz-Schönau warm alkaline-saline spas situated above the Adriatic in North-West Bohemia. Here also are mud baths and the chemical composition of the mud is given. There are several pages of printed matter setting forth the rules and regulations in regard to the hiring of lodgings or apartments. This is very useful in preventing misunderstandings and possible disputes. Franzensbad has a large stall and it boasts of "the best moor baths in the world." Large glass vases contain specimens of this mud. Indeed, there is quite an extensive display of rival muds and peat in this section. Samples of mud are pressed upon the visitor as if mud was a highly valuable article to be studied and only truly appreciated by the well-educated connoisseur. The corporation of Franzensbad purchased in 1893 and in 1904 the springs, parks, and moor grounds, so that all the means of treatment should be placed under a uniform town administration. The modern methods and apparatus have been introduced but there is no wasteful competition between rival local establishments. An elaborate illustrated volume gives full details concerning the various springs and resources of the place. There are alkaline springs, chalybeate and steel springs, and one of the iron waters also contains lithia. Altogether there are 12 mineral springs and thus a great variety of diseases are treated there and of late many cases of heart disease have derived benefit at this station. Franzensbad is in Bohemia. It stands 1500 feet above the sea level and *viâ* Ostend can be reached from London in 22 hours. The exhibit at Earl's Court gives a very thorough indication of the resources of this station. The same may be said in regard to the world-famed resorts of Marienbad and Carlsbad. Every conceivable detail and necessary information can be obtained here. The physician or the patient, instead of writing long explanatory letters to one of these health stations, need only go to Earl's Court. Also there may be some hesitation, more detailed knowledge may be desirable, either in regard to the chemical composition of the waters, the sort of baths given, the style and cost of life, and the resources for exercise or amusement. All this cannot so readily be obtained by correspondence and one station compared with other stations. But at Earl's Court nothing is easier. Ample literature in English with maps and views are supplied gratuitously. Any medical practitioner can also have samples of the waters, or salts, or peat, or mud, for examination here in London. Therefore before recommending a patient to proceed to any one of these stations, his medical adviser has now within easy reach all the necessary information. Certainly this section of the exhibition has been well and thoroughly organised and medical men will do well to profit by this opportunity of securing practical information that cannot fail to be of use.

Other parts of Earl's Court illustrate the attractions of Austria, but especially of the Tyrol, for the general holiday seeker and tourist. Walking expeditions in the Tyrol are very practical and inexpensive. Much beautiful scenery and bracing exercise can be enjoyed. The Bohemian and Dalmatian sections are well calculated to inspire the tourist and the traveller with the desire to visit those romantic mountainous portions of the Austrian Empire.

MEDICINE AND THE LAW.

Action for Alleged Negligence against Medical Men.

THE case of Crier and Wife *v.* Hope and Currie which came last week before the Court of Appeal was an important case as to the liability of medical men. The action was brought by a gentleman and his wife to recover damages in consequence of the latter having contracted scarlet fever while being attended by the defendant, Dr. G. B. Currie, in her confinement, and it was alleged that the medical man was negligent in carrying the infection to her. The questions were, whether due and reasonable care had been taken by Dr. Currie and whether the mischief caused to the wife was due to any want of reasonable care on his part. The summing-up of Mr. Justice A. T. Lawrence in the court below was a most careful one and he told the jury over and over again that Dr. Currie undertook to use due and reasonable care and skill. At the trial a verdict and judgment were entered for the defendants, the jury finding that Dr. Currie had taken the usual precautions. Dr. Currie was defended throughout the case by the London and Counties Medical Protection Society. It was argued for the plaintiffs that the jury meant to find that Dr. Currie, though taking the usual precautions, did something short of taking reasonable precautions, or at all events that there was no finding that he took reasonable precautions. The Master of the Rolls, in the course of his judgment, said: "The case lay in a nutshell, whether it was put upon contract or upon the implied duty of a medical man to his patients. In each case the duty was the same. As to the point of an alleged technical assault, which could at most only result in nominal damages and could, therefore, only affect the costs, it was sufficient to say that the case at the trial was conducted without reference to that point and it was only after verdict that it was raised. That was too late. The verdict and judgment must therefore stand." There have been several actions at different times against medical men for alleged negligence, but they have not been successful as a rule unless gross negligence was proved. It may perhaps be of some interest to refer to a few. In Lanphier v. Phipps (8 Car. & P. 475) it was said that every person who enters into a learned profession undertakes to bring to the exercise of it a reasonable degree of care and skill; he does not, if he is an attorney, undertake at all events to gain the cause; nor does a surgeon undertake that he will perform a cure; nor does the latter undertake to use the highest possible degree of skill, as there may be persons of higher education and greater advantages than himself, but he undertakes to bring a fair, reasonable, and competent degree of skill; and in an action against him by a patient the question for the jury is whether the injury complained of must be referred to the want of a proper degree of skill and care in the defendant or not. In Pimm v. Roper (2 F. & F. 783) a surgeon having been employed by a railway company to examine a passenger who had sustained an injury in a collision on their line, and the surgeon having so far as he could see or judge, on the plaintiff's own statement of his injuries, told him that they were so slight that he (the plaintiff) accepted a small sum in compensation, it was held, even assuming that his injuries were greater, there was no ground of action. In an action by a person who had been a patient at a hospital for maltreatment there by two of the surgeons, it appeared that the alleged maltreatment was in the administration of a hot bath which they had ordered, but which it was no part of their ordinary duty personally to direct and to superintend and at the actual administration of which they were not present, it was held in Perionowsky v. Freeman (4 F. & F. 977) that the plaintiff was not entitled to expect more than the usual and ordinary degree of care and attention at the hands of the surgeons and that if they were not personally cognisant of the alleged ill-usage they were not liable. To render a medical man liable for negligence or want of due care or skill it is not enough that there has been a less degree of skill than some other medical man might have shown or a less degree of care than even he himself might have bestowed, nor is it enough that he himself acknowledged some degree of want of care; there must have been a want of competent and ordinary care and skill and to such a degree as to have led to a bad result (Rich v. Pierpont, 3 F. & F. 35). But every medical practitioner who by a culpable want of attention and care or by the absence of a competent degree of skill and knowledge causes injury to a patient is liable to a civil action for damages unless such injury be the immediate result of intervening negligence on the part of the patient himself or unless such patient has, by his own carelessness, directly conduced to such injury. In Slater v. Baker and Stapleton (2 Wils. 359) the plaintiff employed the defendants, the first-named being a surgeon and the second an apothecary, to cure his leg, which had been broken and set, and the callus of the fracture formed. The defendants disunited the callus and Baker fixed on to the plaintiff's leg a heavy steel instrument with teeth to stretch or to lengthen the leg. In a special action upon the case against the defendants the plaintiff recovered £500 damages against them jointly; and in answer to an objection that the action ought to have been trespass *vi et armis* for breaking the plaintiff's leg without his consent the court replied: "It appears from the evidence of the surgeons that it was improper to disunite the callus without consent. This is the usage and law of surgeons. Then it was ignorance and unskilfulness in that very particular to do, contrary to the rule of the profession, what no surgeon ought to have done; and, indeed, it is reasonable that a patient should be told what is about to be done to him, that he may take courage and put himself in such a situation as to enable him to undergo the operation. For anything that appears to the court, this was the first experiment made with this new instrument; and if it was, it was a rash action, and he who acts rashly acts ignorantly; and although the defendants, in general, may be as skilful in their respective professions as any two gentlemen in England, yet the court cannot help saying that, in this particular case, they acted ignorantly and unskilfully, contrary to the known rule and usage of surgeons." A medical man is liable to a civil action for injury resulting to a patient from his negligence or unskilful treatment, although the patient neither employed nor was to pay him. Thus in Longmeid v. Holliday (6 Exch. 767), Baron Parke said: "If an apothecary administers improper medicines to his patient, or a surgeon unskilfully treats him, and thereby injures his health, he will be liable to the patient, even where the father or friend of the patient may have been the contracting party with the apothecary or surgeon; for, though no such contract had been made, the apothecary, if he gave improper medicines, or the surgeon, if he took him as a patient and unskilfully treated him, would be liable to an action for a misfeasance"; and in Pippin v. Sheppard (5 Bing. N. C. 733), which was an action by a man and his wife against a surgeon for an injury to the wife by reason of the defendant's improper and unskilful treatment, Chief Baron Richards said: "From the necessity of the thing the only person who can properly sustain an action for damages for an injury done to the person of a patient is the patient himself, for damages could not be given on that account to any other person, although the surgeon may have been retained and employed by him to undertake the cure"; and in the same case Baron Garrow said: "In cases of the most brutal inattention and neglect the patients would be precluded frequently from seeking damages by course of law, if it were necessary to enable them to recover that there should have been a previous retainer on their part of the person professing to be able to cure them. In all cases of surgeons retained by any of the public establishments it would happen that the patient would be without redress, for it could hardly be expected that the governors of an infirmary should bring an action against the surgeon employed by them to attend the child of poor parents who may have suffered from his negligence and inattention."

Boric Acid added as a Preservative to Potted Meats.

A firm of provision merchants holding large contracts for the supply of provisions to army canteens was summoned recently at the Brentford police court under the Sale of Food and Drugs Act for selling certain tinned meats which were not of the nature and quality of the articles demanded. The articles in respect of which the summons was taken out consisted of chicken and tongue, chicken and ham, and ham contained in tins the price of which was 1d. each and the adulteration complained of consisted of the addition of boric acid as a preservative in a proportion equivalent to 52 grains of borax per pound. There was also evidence that colouring matter in the form of oxide of iron had been used. After a considerable amount of expert evidence had been given on both sides the bench held unanimously that there must be a conviction on the ground that the article sold was rendered injurious by the addition of boric acid in the proportion proved, pointing out that it had been admitted by a witness called for the defence that the preservative might injure a child or a person not in robust health, although it might have no effect upon a healthy adult. A fine of £5, with 50 guineas costs, was imposed. In this case the evidence of the prosecution was not directed to showing any general or certain danger arising out of the presence of boric acid but was confined to the points that in the case of sound meats preserved by being "tinned" it was quite unnecessary and that its effect might be prejudicial to the consumer according to the amount consumed and other circumstances. It was also pointed out that although it was not suggested that the meat forming the subject matter of the prosecution was unsound, and although boric acid would not act as a deodoriser, the preservative might act so as to arrest incipient decomposition without averting the effects of that which had already taken place and also that the summons was not taken out in respect of potted meat which would be kept after the tin was opened but in respect of small tins costing a penny each which would be consumed at once. The suggestion put to a witness that borax might be used medicinally was met with the natural answer that this would not make it desirable to administer it indiscriminately in food. The evidence called for the defence was to the effect that borax was generally used as a preservative, particularly in the case of ham, which it was suggested was due to the modern demand for hams "mildly" cured and was more particularly called for the purpose of establishing the general want of proof of ill-effects arising from its use. The conclusion to which the case points would seem to be that the use of boric acid as a preservative should be discouraged in every possible manner, not on account of any serious danger necessarily arising in all cases where it is employed, but on account of the difficulty of allowing its use in moderation and of, at the same time, detecting and punishing its abuse when added in excessive quantities and for an illicit object.

order to prevent the spread of infection she nevertheless disregarded the notice and attended a confinement as a midwife.

The Board directed the name of this midwife to be removed from the roll.

THE AUSTRIAN EXHIBITION AT EARL'S COURT.

SOME years have elapsed since there has been so serious an exhibition at Earl's Court. There was a danger that these annual exhibitions would degenerate into mere out-of-door entertainments, where bands, the Big Wheel, the water-chutes, the gardens, and various side shows would constitute the chief attractions. This year, however, we have, for the first time, an Austrian exhibition and both public bodies and private enterprise of that country have really endeavoured worthily to be represented. As a result the exhibition constitutes quite an object lesson in regard to the resources of the empire. The heavier industries—coal mining, ironworks, leather dressing, cotton and wool, &c.—are, it is true, scarcely represented. It is mainly the Austria of the tourist that we see; and this includes those who travel not merely for pleasure but for health. There is, indeed, quite an important section devoted to the great Austrian balneological stations This will be found on the right-hand side of the Royal Galleries if entered from the Brompton or the Tyrolese Village side, close to the colonnade that surrounds the oval known as the Royal Galleries, in a quiet inner compartment. Here these exhibits can be studied at ease. At one end there is an oil painting of Abbazia. It shows the beautiful position occupied by this celebrated resort of the Adriatic Riviera. Close at hand, on a large stand, an extensive display of bottles and pamphlets are intended to convey some idea of the benefits to be derived from the arsenious iron baths of Levico-Vetriolo. These are valleys 1600 feet and 3000 feet respectively above the level of the sea and situated near Trent in the South Tyrol. The railway journey from London takes 38 hours and the spring and autumn are the favourite seasons. The waters are rich in proto-sulphate of iron and of arsenious acid, and there is also a summer bathing establishment, for the waters are used externally and internally.

The advantage, and it is a very great advantage, of this section of the exhibition is that every detail of needful information can be obtained concerning the various health resorts. For instance, in regard to most resorts we can ascertain not only the composition of the waters and the diseases for which they are employed but the charges made for the baths, the different forms of treatment, and for the Kurtax, and what sports, concerts, and entertainments are provided in return for this tax. Here, likewise, a large number of photographs can be seen. There is notably a very fine photograph of Meran, while albums provide views of the details of the baths and their organisation. There are statistics also, and thus we learn, for instance, that 30,000 visitors annually frequent the sulphur baths of Baden, near Vienna. But in autumn this method of treatment may be varied with "the grape cure," which agreeable *régime* doubtless attracts many persons. Then the hotels are organised so that the food of the residents may be in accordance with the directions laid down by the medical attendants.

Close at hand are the exhibits of the Teplitz-Schönau warm alkaline-saline spas situated above the Adriatic in North-West Bohemia. Here also are mud baths and the chemical composition of the mud is given. There are several pages of printed matter setting forth the rules and regulations in regard to the hiring of lodgings or apartments. This is very useful in preventing misunderstandings and possible disputes. Franzensbad has a large stall and it boasts of "the best moor baths in the world." Large glass vases contain specimens of this mud. Indeed, there is quite an extensive display of rival muds and peat in this section. Samples of mud are pressed upon the visitor as if mud was a highly valuable article to be studied and only truly appreciated by the well-educated connoisseur. The corporation of Franzensbad purchased in 1893 and in 1904 the springs, parks, and moor grounds, so that all the means of treatment should be placed under a uniform town administration. The modern methods and apparatus have been introduced but there is no wasteful competition between rival local establishments. An elaborate illustrated volume gives full details concerning the various springs and resources of the place. There are alkaline springs, chalybeate and steel springs, and one of the iron waters also contains lithia. Altogether there are 12 mineral springs and thus a great variety of diseases are treated there and of late many cases of heart disease have derived benefit at this station. Franzensbad is in Bohemia. It stands 1500 feet above the sea level and *viâ* Ostend can be reached from London in 22 hours. The exhibit at Earl's Court gives a very thorough indication of the resources of this station. The same may be said in regard to the world-famed resorts of Marienbad and Carlsbad. Every conceivable detail and necessary information can be obtained here. The physician or the patient, instead of writing long explanatory letters to one of these health stations, need only go to Earl's Court. Also there may be some hesitation, more detailed knowledge may be desirable, either in regard to the chemical composition of the waters, the sort of baths given, the style and cost of life, and the resources for exercise or amusement. All this cannot so readily be obtained by correspondence and one station compared with other stations. But at Earl's Court nothing is easier. Ample literature in English with maps and views are supplied gratuitously. Any medical practitioner can also have samples of the waters, or salts, or peat, or mud, for examination here in London. Therefore before recommending a patient to proceed to any one of these stations, his medical adviser has now within easy reach all the necessary information. Certainly this section of the exhibition has been well and thoroughly organised and medical men will do well to profit by this opportunity of securing practical information that cannot fail to be of use.

Other parts of Earl's Court illustrate the attractions of Austria, but especially of the Tyrol, for the general holiday seeker and tourist. Walking expeditions in the Tyrol are very practical and inexpensive. Much beautiful scenery and bracing exercise can be enjoyed. The Bohemian and Dalmatian sections are well calculated to inspire the tourist and the traveller with the desire to visit those romantic mountainous portions of the Austrian Empire.

MEDICINE AND THE LAW.

Action for Alleged Negligence against Medical Men.

THE case of Crier and Wife *v.* Hope and Currie which came last week before the Court of Appeal was an important case as to the liability of medical men. The action was brought by a gentleman and his wife to recover damages in consequence of the latter having contracted scarlet fever while being attended by the defendant, Dr. G. B. Currie, in her confinement, and it was alleged that the medical man was negligent in carrying the infection to her. The questions were, whether due and reasonable care had been taken by Dr. Currie and whether the mischief caused to the wife was due to any want of reasonable care on his part. The summing-up of Mr. Justice A. T. Lawrence in the court below was a most careful one and he told the jury over and over again that Dr. Currie undertook to use due and reasonable care and skill. At the trial a verdict and judgment were entered for the defendants, the jury finding that Dr. Currie had taken the usual precautions. Dr. Currie was defended throughout the case by the London and Counties Medical Protection Society. It was argued for the plaintiffs that the jury meant to find that Dr. Currie, though taking the usual precautions, did something short of taking reasonable precautions, or at all events that there was no finding that he took reasonable precautions. The Master of the Rolls, in the course of his judgment, said: "The case lay in a nutshell, whether it was put upon contract or upon the implied duty of a medical man to his patients. In each case the duty was the same. As to the point of an alleged technical assault, which could at most only result in nominal damages and could, therefore, only affect the costs, it was sufficient to say that the case at the trial was conducted without reference to that point and it was only after verdict that it was raised. That was too late. The verdict and judgment must therefore stand." There have been several actions at different times against medical men for alleged negligence, 3 were 70 and upwards. 36 were epileptic, 16 were con- nital idiots, and 24 were general paralytics. In fact, only l of the cases admitted were regarded as recoverable and of is number 58 were discharged during the year. The ylum committee deplores the fact that unsuitable tients are sent to its institution and calls the attention the unions interested to the matter. The chief causes insanity do not appear to vary in the experience this asylum; it is stated that hereditary taint and ngenital defect become more marked every year; they were aced in about 31 per cent. of the patients admitted which, owever, is below the experience of many other asylums. arious forms of worry accounted for 20 per cent. and coholic intemperance for about 18 per cent. Various seases, not specified in the table of causation, were usative in 35 of the cases, as to which further information ould be of interest. Of the 197 discharges 126 left covered, the recovery-rate being 38·39 per cent. of the lmissions. The deaths numbered 133, the chief cause ing general paralysis which accounted for 21. The death- ite amounted to 9·88 per cent. of the daily average umber resident. It is distressing to note that of 341 patients remaining at the close of the year only 5 were regarded as having a fair chance of recovery. . case of attempted suicide in a male patient presents atures of interest. This man, who was not regarded as icidal, was found hanging by the neck from a rafter, aving been out of supervision for only a few minutes. He as cut down and brought round sufficiently to be removed the ward where he relapsed into a semi-comatose state. he head and neck were greatly congested. He was bled to e extent of 20 fluid ounces, regained consciousness, and ade a good recovery. He retained no recollection of e act. The accommodation on the male side is deficient, 50 ases being boarded out as well as ten idiot children.

Joint Counties Asylum, Carmarthen (Annual Report r the Year 1905).—The admission-rate for the year as lower than usual of late years, 105 patients being eceived. The average number daily resident was 664. he numbers resident increase steadily but slowly. The ecovery-rate, reckoned on the admissions, was the satis- actory one of 46·31 per cent., having been 44 per cent. for 904. The proportion of deaths to the average number aily resident was the low one of 8·58 per cent. The edical superintendent, Dr. E. Goodall, having measured ut the accommodation available on the basis of the present equirements of the Commissioners in Lunacy, finds that on he female side the patients are in excess—though not greatly so—of the day and night space available, whilst on he male side the day rooms are somewhat overcrowded, but here is night space for some ten additional patients. 12 of the cases admitted died within a few weeks of admission from exhaustion, of which four were cases of acute delirium. Dr. Goodall states that it is very difficult, if not impossible, to give cases of this disease that unremitting attention which they need under the usual conditions of a county asylum, in which the proportion of nurses to patients is low, and he considers that such cases illustrate the advantage of the "acute hospital" system for asylums. It may be added that they also afford a strong argument in favour of the system of receiving recent and curable cases of mental disease into suitable wards attached to general hospitals. A history of insanity or allied disorders was present in 50·5 per cent. of the admissions, and even this high figure is regarded as an under-statement. It is observed that comparative statistics as to the existence of insane and neurotic inheritance in the general population on the one hand, and the population of asylums (including persons who have been in asylums) on the other, would be instructive as throwing light upon the real value of the hereditary factor in the causation of insanity as distinct from the environmental factor. Alcohol only accounted for 12 per cent. of the admissions, a low figure compared with that shown by asylums which serve exclusively urban districts. The religious "revival" in Wales was responsible for the mental disorder in 16 cases; these were mostly individuals predisposed by inheritance to insanity. 14 of the patients admitted were aged 60 years and upwards. It is observed that there appears to be an increasing unwillingness on the part of Poor-law guardians throughout the country to make adequate provision for the aged and harmless insane in workhouses. This asylum makes no adequate provision for the segregation of consumptives; during the day these are, so far as possible, segregated in the airing-courts under verandahs. The proportion of deaths from tuberculous disease of all sorts was 17·5 per cent. of all deaths, as against 25, 23, and 28·6 per cent. for the previous three years, the last-mentioned figure being that for 1902; and the mortality from this disease per 1000 inmates was 15, as compared with 17·9 in the preceding year. These are gratifying reductions, bringing the institution into line with other asylums of similar size, and it is hoped that time may show that the improvement is traceable to various measures which of late years have been taken to provide for the stricter isolation of the tuberculous and for the disinfection of their environment. Inquiry has been made into the history of the cases which have relapsed during the past 12 years with a view to acquire information as to the durability of recovery after discharge. During this period 143 patients were admitted who had had previous attacks, and of these 121 had relapsed once. Of the latter 18 had kept well for from three to six years and 29 for from six to 33 years. The remaining 74 remained well for varying periods to a maximum of three years only. Dr. Goodall is of opinion that these results are probably much inferior to what might be looked for from the returns of institutions receiving the better educated and more comfortable classes. This question of the durability of recovery in mental cases merits further inquiry. Of 64 cases of first attack only 33 were received within three months of the commencement of the illness. The general health of the institution was satisfactory. The Commissioners in Lunacy in the course of their annual report on the institution refer to a regrettable dispute which exists between the three local authorities owning the asylum as to quotas payable towards the upkeep of the building and which is of some years' standing, the practical consequence being that administrative reforms which are required in the interests of the patients are delayed.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 76 of the largest English towns 8717 births and 3550 deaths were registered during the week ending July 21st. The annual rate of mortality in these towns, which had declined from 13·2 to 11·7 per 1000 in the four preceding weeks, rose again last week to 12·0 per 1000. During the past four weeks the death-rate has averaged 12·1 per 1000, the rate in London during the same period being 11·9 per 1000. The lowest death-rates last week in the 76 towns were 4·7 in Hanley, 4·9 in Handsworth (Staffs), 5·4 in Rochdale, 5·7 in Leyton, 5·9 in Reading, and 6·2 in Cardiff; the highest rates were 16·5 in Liverpool, 17·0 in Huddersfield, 17·4 in Merthyr Tydfil, and 17·8 in Stockport and in Burnley. The 3550 deaths registered in the 76 towns last week were 94 more than the number in the previous week, and included 424 which were referred to the principal epidemic diseases, against 373, 406, and 251 in the three preceding weeks; of these 424 deaths, 165 resulted from diarrhœa, 104 from measles, 59 from whooping-cough, 43 from diphtheria, 38 from scarlet fever, and 15 from "fever" (principally enteric), but not any from small-pox. The deaths from these epidemic diseases were equal to an annual rate of 1·4 per 1000 in the 76 towns and to 1·5 per 1000 in London. No death from any of these diseases was registered last week in Southampton, Coventry, West Hartlepool, or in ten other smaller towns, while they caused the highest death-rates in Norwich, Birkenhead, Liverpool, Wigan, Salford, Burnley, Huddersfield, and Rotherham. The greatest proportional mortality from measles occurred in Salford, Burnley, and Huddersfield; from whooping-cough in Birkenhead, York, and Swansea; and from diarrhœa in Willesden, Norwich, Birkenhead, Liverpool, St. Helens, Wigan, Salford, Burnley, and Rhondda. The 43 deaths from diphtheria included ten in London, three in Liverpool, and two each in Croydon, Walthamstow, Plymouth, Bristol, Birmingham, and Derby; of the 38 fatal cases of scarlet fever 12 occurred in London, four in Liverpool, three in Birmingham, three in Manchester, and two each in Hornsey, Bristol, Leicester, and Leeds; the 15 deaths from "fever" included six in London and two each in West Ham and Wigan. No fatal case of small-pox was registered in any of the 76 towns during the week. The number of small-pox patients in the Metropolitan Asylums hospitals, which had declined from 13 to five at the end of the four preceding weeks, had

Looking Back.

FROM

THE LANCET, *SATURDAY*, July 26th, 1828.

The Coroner's Inquest is, in respect to its object and tendency, one of the most useful institutions in this country; but its utility is greatly limited, and in many instances entirely defeated, by the inefficiency of the individuals who, for the most part, fill the office of Coroner. The fact is, that in almost all the cases which come before the Coroner, the question to be determined is of a medical, and not of a legal character. The statute of the 4th Edward I., which comprehends nearly all the law relating to the office of Coroner, is a short act of Parliament, which any man who runs may read and understand. Any man of ordinary understanding, who has read this statute, and who has served occasionally as juryman, or witnessed a few trials, so as to acquire some general information as to the common rules of evidence, is competent, as far as legal qualifications are concerned, to discharge the duties of the office of Coroner. But the medical qualifications which would enable a Coroner to discharge with efficiency the duties of his office, are of a far higher order, and can hardly be expected to be possessed by any man not a member of the medical profession. Questions constantly arise, in the course of inquisitions before the Coroner, which demand an intimate acquaintance on the part of that officer, with anatomy, pathology, chemistry, and therapeutics. The very *gist* of these inquiries, in all cases of difficulty or doubt, involves a medical question, which can only be adequately determined by medical men. To determine whether the death of the deceased arose from natural or violent causes; to judge whether a particular injury is capable of producing the effects supposed to have resulted from it; to decide whether poison has or has not been taken, and to distinguish between cases in which a poisonous substance may have been administered with a guilty intent, and where it may be presumed to have been given as a therapeutic agent—such are the points on which a Coroner is perpetually called upon to inform and direct a Jury, and on which, without a medical education, it is impossible that he can himself arrive at sound and satisfactory conclusions. PARIS and FONBLANQUE, in their Medical Jurisprudence, feeling the necessity of medical information to a due discharge of the duties of the office of Coroner, recommend the addition of a medical assessor to assist that officer in the holding of Inquests. But this is advising the repair of an old building, when the cheaper and wiser course would be to pull it down, and erect a new edifice on its site. Why retain machinery, which is confessedly inadequate to the object it was intended to accomplish? If medical men are best qualified to discharge the duties of Coroners, why not appoint them in place of those low and incompetent persons into whose hands we find Mr. Justice Blackstone complaining that the office, in his time, too frequently fell?[1]

ASYLUM REPORTS.

Derby Borough Asylum (Seventeenth Annual Report for the Year ending Dec. 31st, 1905).—The admissions into this institution during the year under report numbered 103, of which 80 were chargeable to the Derby union, the remainder being out-county and private patients. Nine of the patients admitted had previously been under treatment and it is of interest to note that they had on an average kept well for nearly seven years since discharge. In 64 of the admissions the illness was stated to be of less than one year's duration, in other words they were cases likely to benefit by treatment; of these 70 per cent. presented curable forms of mental disorder. The proportion of suicidal patients admitted was high, at least 30 having meditated or threatened suicide, whilst in 18 others an attempt had actually been made. Rather more than one-half of the patients admitted suffered from some physical disease. In the opinion of Dr. S. Rutherford Macphail, the medical superintendent, at least 60 per cent. of cases admitted to asylums break down "because the nervous system is the weak point in the families from which they spring." Of the 103 admissions to this asylum, hereditary predisposition to insanity was ascertained in 37 cases, whilst in 15 other cases there was "a family history of neuroses and other hereditary affections." In 74 of the cases some exciting cause was given in the history, coming under the head of "mental or moral cause" in 28, whilst in 46 the cause was a physical one, such as alcohol, a bodily disease, or the change of life. Alcohol was responsible in only 12 per cent. of the admissions instead of the average of 20 per cent. of previous years. The daily average number resident was 331; this number reached [illegible] for the first time in 1893, five years after the opening of the asylum, and has steadily risen to the present figure. 39 patients were discharged recovered, giving the high proportion of 49·3 per cent. of the admissions. In addition nine were discharged as relieved. The death-rate was the moderate one of 9·9 per cent. of the daily average number resident. The causes of death were usual ones. The death-rate from tubercle has throughout been very low in the asylum. The general health of those in the institution was quite satisfactory. There were a few sporadic cases of influenza but no epidemic occurred, whereas, it is interesting to note, epidemics of this disease have recurred it [illegible] annually for 14 years. The important point of the tendency to relapse is referred to by Dr. Macphail, who finds that since the opening of the asylum 19 per cent. of the patients discharged as recovered have relapsed and have been re-admitted, not at all a high proportion. The Commissioners in Lunacy report favourably of the condition of the institution.

Glasgow Royal Asylum, Gartnavel (Ninety-second Annual Report for the Year 1905).—The total admissions into the institution during 1905 numbered 119 and were composed of private patients classified as follows: professional class, 16; domestic, 29; commercial, 34; agricultural, seven; industrial, ten; and unknown or indefinite, 23. Of the 119, 31 sought admission voluntarily and the physician-superintendent, Dr. L. R. Oswald, finds that the percentage of recoveries is higher amongst voluntary than amongst certified patients, the probable explanation being that in the former the malady is in an early stage and therefore more amenable to treatment. Depression was more common among the patients admitted than excitement. Many of the cases received showed the alternating type of mental disorder called by some *folie circulaire*; this in Dr. Oswald's experience is more common among the educated and middle classes than among the working classes treated in county asylums. We agree that it is uncommon to meet this condition in the latter institutions. Amongst causes of insanity hereditary predisposition was found in only 35 per cent. of the admissions and in from 17 to 18 per cent. this was the only ascertained cause. Alcohol was the cause in very few cases—namely, 12—but in several in which this had been supposed to be the cause it appeared on critical inquiry that excessive indulgence was only a symptom, and this is a point well worthy of attention. About 40 per cent. of the patients admitted were in the favourable class for treatment—that is to say, the attack was the first one and had lasted less than three months. The average number resident daily throughout the year was 432. The recoveries amounted to 42, or 35 per cent. of the admissions. This is not a high proportion but it is to be noted that in addition 40 patients were discharged greatly improved. The deaths numbered 24, giving the very low proportion of 5·6 per cent. on the daily average number resident. Eight of the above number were over 75 years of age. The asylum has for years had a low death-rate. We observe from one of the reports of the Commissioners in Lunacy that acute cases are treated by rest in bed in the open air, which is an excellent plan. These reports refer to the liberal manner in which the institution provides for patients of limited means. When last it was visited by the Commissioners 57 patients were paying under £40 per annum, 155 paid £40, and 110 from £40 to £60.

Surrey County Asylum, Brookwood (Annual Report for the Year 1905).—From the thirty-seventh annual report of Mr. James E. Barton, the medical superintendent, it appears that the admissions at this asylum during the year on record numbered 350 and the average number resident was 1345. The mental condition of the majority of the patients admitted was, it is regrettable to learn, very unfavourable from the point of view of recovery. Many were old and feeble, no less than 116 being over 50 years of age, of whom

"Audi alteram partem."

DENDRITES AND DISEASE.

To the Editors of THE LANCET.

SIRS,—Sir William Gowers's lecture on Dendrites and Disease[1]—surely one of the most luminous contributions to modern neurology—raises many questions of absorbing interest. To two of these I propose with your permission to make a brief reference.

1. Sir William Gowers assumes that the dendrites of adjacent neurons are separated by, and influence one another through, an intervening "matrix"—i e., that there is no direct conduction of nerve impulses from one neuron to another—but that a dendrite of one neuron so influences the matrix in which it terminates as to generate a nerve impulse in the adjacent dendrite of another neuron. He, moreover, regards the dendrites as being contractile, and he suggests that the influence which the dendrites of one neuron exert on those of adjacent neurons can be regulated by means of this contractility; when, e g., they contract firmly all communication between adjacent neurons is cut off, as may happen during sleep and functional anæsthesia; when, on the other hand, they relax neighbouring neurons are brought into functional relation.

I venture to raise the question whether during this dendritic relaxation adjacent dendrites of separate neurons may not merely come into close proximity, but be brought into actual contact, so as to admit of the direct *conduction* of nerve impulses from one neuron to another, which would be a far more simple process than the induction *de novo* of a nerve impulse in the second cell; and not only so, but by means of this direct conduction it would be easier, one would think, for a particular dendrite of one neuron to affect a particular dendrite of another neuron, *and no other*, than by the less direct method. The great difficulty in the way of accepting this view is the fact that, so far as our actual knowledge goes, nervous impulses are always started in neurons by a *de novo* generation through a non-nervous medium, as in the case of the sensory end-organs; it must, moreover, have been solely through a non-nervous medium that nerve impulses were generated when neurons first evolved in the animal kingdom.

2 The view that the influences passing between adjacent neurons can be regulated by means of the contractility of their dendrites is one which throws an altogether new light on many difficult problems in neurology. The ultimate dendrites of a neuron are probably to be counted by the thousand, and one can conceive how, by a greater or less degree of contraction of this or that dendrite belonging to adjacent neurons, one neuron may be capable of influencing another in a multitude of different ways. Modern histology seems to point to the conclusion that every neuron contains a definite number of fibrils along which nerve impulses are conducted. These impulses are thus compelled to travel along definite, pre-determined routes. The fibrils do not, as Sir William Gowers points out, end in the body of the neuron cell but pass right through it, so that all nerve impulses must start at their extremities—i.e., at the termination of the dendrites or axites. We do not know whether by education the fibrils can be increased in number; quite possibly they cannot be. Now, seeing that the fibrils pass right through the body of the neurons and that nerve impulses must travel along the fibrils, it is obvious that if there were actual permanent union between the adjacent dendrites of neighbouring neurons, all nervous action would tend to be stereotyped, and it would be impossible for the nervous system to acquire the power of executing new combinations except by the development of new fibrils, and, seeing how endless are the new combinations which the nervous system can be taught to execute, this would imply an increase in the number of the fibrils so great as to be physically impossible. These difficulties are removed if we assume that all nervous coördination is effected by an adaptive contraction and relaxation of neighbouring dendrites, for in this way it would be possible to link up in a multitude of different ways particular fibrils of one neuron with particular fibrils of another neuron, and thus compel nerve impulses to pass along particular routes. On this view the education of the nervous system would essentially consist in the acquisition by the dendrites of special powers of adaptive contractility.

From analogy with telephonic methods, we may speak of this as the principle of "dendritic exchange," and though it does not explain how the dendrites come by their power of adaptive contractility, and of forming new exchanges, yet its formulation seems to be a step towards an ultimate explanation of the well-nigh limitless capacity of the nervous system to make new acquisitions, many of them of a bewildering complex nature.

I am, Sirs, yours faithfully,

Wimpole-street, July 16th, 1906. HARRY CAMPBELL.

LEPROSY AND FISH-EATING.

To the Editors of THE LANCET.

SIRS,—Referring to your review of Mr. Jonathan Hutchinson's book[1] and to his recent letter in your columns[2] I shall be obliged if you will permit me to point out a fallacy that underlies at least one of his arguments and invalidates some of his conclusions.

The contention to which I refer is that Christianity—especially the Catholic type, but, in lesser degree, Protestantism also—fosters leprosy by its encouragement of fish-eating as contrasted with other creeds which either forbid, or at least discourage, it. Mr. Hutchinson supports this view by quoting what he considers the excessive proportion of Christians among the inmates of some of the Indian leper asylums visited by him. Had he carried his inquiries a little further he would have found in almost all cases that the Christian lepers, from whose numbers he deduces the prevalence of the disease among Indian Christians, *had become converts after they were lepers*, and that whatever weight they possess as evidence should consequently go into the opposite scale. Let us take a specific instance in which the facts are beyond question. Referring to his visit to the leper asylum at Tarn Taran, Punjab, Mr. Hutchinson writes (p. 106): "On the calculation that in the community there were two lepers per 10,000, the Mussulman population (14,000,000) might have supplied 2800 and the Hindoo population of 13,000 000 2600, whilst the little Christian population of only 72,000 ought to have sent not more than 14; it did, however, to this one asylum alone, which is only one out of five under missionary care in the Punjab, send no fewer than 34. Under the term 'Christian' are here included Protestants as well as Catholics and English as well as natives. If we restrict the calculation to the native Christians, which is only fair, seeing that the Europeans supply no lepers, we should then find that its calculated proportion would be only eight. Very similar statements apply to the Calcutta Asylum, to that of Madras, and to that of Bombay."

Mr. Hutchinson takes for granted that these 34 Christian lepers are contributed by the native Christian community of the district and argues that they are four times as numerous as they should be. The fallacy of this assumption and of any argument based on it is clear from a single fact—viz., that in every one of these 34 cases *the leprosy preceded the Christianity*. Let me support this assertion by the testimony of a witness possessed of actual knowledge. The Tarn Taran Asylum is one of 45 such institutions supported or supervised by the Mission to Lepers in India. For 21 years religious teaching has been provided for its inmates under the care of the Rev. E. Guilford, who is now the superintendent of the asylum, the management of which has been transferred to the mission by the Punjab Government. In a letter just received and referring to Mr. Hutchinson's statement Mr. Guilford writes: "Of those 34, every one had become a leper before he or she was admitted into the Church. I have worked in the Punjab now for nearly a quarter of a century and during that time I have never seen one single case of leprosy amongst our native Christians." This emphatic testimony also rebuts another of Mr. Hutchinson's suppositions—viz., that "the number in any given asylum does not represent the total in the Christian population of the district. Many of the Christian lepers are, no doubt, still at their own homes" (p. 106). Whatever may be the case in those parts of India in which the Christian population is largely Romanist, this is certainly not correct as further fallen to two at the end of last week; no new cases of small-pox have been admitted into these hospitals during the past four weeks. The number of scarlet fever patients remaining under treatment in these hospitals and in the London Fever Hospital at the end of the week was 2942, against numbers increasing from 2225 to 2842 at the end of the 13 preceding weeks; 413 new cases were admitted during the week, against 366, 378, and 406 in the three preceding weeks. The deaths in London referred to pneumonia and other diseases of the respiratory organs, which had been 118 and 119 in the two preceding weeks, further rose to 133 last week, but were slightly below the corrected average number in the corresponding periods of the four preceding years. The causes of 39, or 1 1 per cent., of the deaths in the 76 towns last week were not certified either by a registered medical practitioner or by a coroner. The causes of all the deaths were duly certified in West Ham, Leicester, Nottingham, Salford, Sheffield, Newcastle-on-Tyne, Cardiff, and in 49 other smaller towns; nine uncertified deaths were registered in Liverpool, five in London, four in Birmingham, three in Manchester, two in Bradford, two in St. Helens, and one each in 14 other towns, including Bristol, Leeds, and Hull.

---

[1] THE LANCET, June 16th, 1906, p. 1695.

[2] THE LANCET, July 7th, 1906, p. 45.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in eight of the principal Scotch towns, which had been 15 3 and 14·3 per 1000 in the two preceding weeks, further fell to 13 7 per 1000 last week, but was 1·7 per 1000 above the mean rate during the same period in the 76 large English towns. The rates in the eight Scotch towns last week ranged from 10·2 in Paisley and 10·7 in Edinburgh to 15·3 in Glasgow and 24·2 in Perth. The 470 deaths in the eight towns showed a decrease of 21 from the number in the preceding week, and included 12 which were referred to whooping-cough, 11 to diarrhœa, seven to measles, five to diphtheria, and five to "fever," but not any to small-pox or to scarlet fever. In all, 40 deaths resulted from these principal epidemic diseases last week, showing a decline of 23 from the number returned in the previous week. The 12 deaths attributed to whooping-cough were five below the number in the preceding week, and included eight in Glasgow and three in Aberdeen. The fatal cases of diarrhœa, which had been 20, 18, and 22 in the three preceding weeks, decreased last week to 11, of which six occurred in Glasgow and three in Dundee. The seven deaths from measles were considerably fewer than the number in any other recent week, and included three in Glasgow and two in Edinburgh. The five fatal cases of diphtheria were slightly in excess of the numbers in the two previous weeks; three of these deaths were registered in Glasgow, where also four fatal cases of cerebro-spinal fever, included under the heading "fever," were recorded. The deaths in the eight towns referred to diseases of the respiratory organs, including pneumonia, which had been 54 and 59 in the two preceding weeks, further rose to 66 last week and slightly exceeded the number in the corresponding week of last year. The causes of 16, or 3 4 per cent., of the deaths registered in the eight towns last week were not certified, the proportion of uncertified deaths in the 76 large English towns during the same period being 1·1 per cent.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 16·4, 16 9, and 18·7 per 1000 in the three preceding weeks, further rose to 20 9 per 1000 during the week ending July 21st During the 13 weeks of last quarter the death-rate averaged 21·4 per 1000, against 14·8 in London and 17·1 in Edinburgh. The 152 deaths of Dublin residents during last week showed an increase of 16 over the number in the preceding week, and included ten deaths from the principal epidemic diseases, against five, four, and 12 in the three preceding weeks; of these ten deaths, three were referred to whooping-cough, three to diarrhœa, two to measles, one to diphtheria, and one to "fever," but not any to small pox or to scarlet fever. These ten deaths from the principal epidemic diseases were equal to an annual rate of 1·4 per 1000, the rate from the same diseases last week being 1·5 in London and 0·5 in Edinburgh. The 152 deaths in Dublin included 26 of children under one year of age and 47 of persons aged 60 years and upwards. Five inquest cases and three deaths from violence were registered; and 59, or 39 per cent., of the deaths occurred in public institutions, the proportion in London being 40 per cent. The causes of five, or 3·3 per cent., of the 152 deaths were not certified either by a registered medical practitioner or by a coroner; the proportion of uncertified deaths during the same period being 0·5 per cent. in London and 4·3 per cent. in Edinburgh.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet Surgeons: J. McElwee to the *President*, temporary, and A. McLean to the *Renown*. Staff Surgeon H. Cleft to the *Hawk*. Surgeon P. H. Bannister to the *President*, additional for three months' course at West London Hospital.

ROYAL ARMY MEDICAL CORPS.

Lieutenant-Colonel Percy H. Johnston, C.M.G., is placed on retired pay (dated July 13th, 1906).

Colonel C. Todd has been appointed to officiate as Principal Medical Officer, Western Command, India, vice Colonel F. W. Trevor, on leave.

INDIAN MEDICAL SERVICE.

Lieutenant-Colonel D. Ffrench-Mullen, Bengal, has been appointed to officiate as Principal Medical Officer, Sirhind and Jullunder Brigades, vice Colonel H. Hamilton, C.B., on leave.

THE ROYAL VICTORIAN ORDER.

Lieutenant-Colonel Bruce Morland Skinner, R.A.M.C., Secretary to the Advisory and Nursing Boards of the War Office, has been appointed a member of the Fourth Class of the Royal Victorian Order.

TINNED MEAT IN PLYMOUTH GARRISON.

According to Plymouth Coast Defence Orders, dated July 17th, when preserved meat is issued officers commanding units are to arrange for a regimental board of officers to assemble to open and to inspect all tins of meat before use and, where possible, the medical officer in charge of troops will attend.

RESUMPTION OF MEDICAL CLASSES IN RUSSIA.

It is announced in the *Torgovo Promyshlennaya Gazeta* that all classes in the Military Medical Academy will begin work on Sept. 14th this year. This may be rather a sanguine prophecy but there are other evidences that it is the intention of the authorities not to allow the military medical organisation to lapse into chaos. For example, the committee appointed to draw up the new regulations for the constitution of the military sanitary elements of the army has recently considered the question of grades for military medical officers. It was agreed to be indispensable that these officers should be graded as generals, staff officers, and superior officers with all their prerogatives. They will constitute a special official corps—"the Corps of Military Medical Officers"—and they will wear distinctive uniforms and enjoy special professional as well as military privileges.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—A quarterly court of the directors of this society was held on July 11th at 11, Chandos-street, Cavendish-square, London, W., Dr. G. F. Blandford, the President, being in the chair. 14 members were present. The death of Dr. John Clarke was reported, who was elected a member in 1847 and had been one of the vice-presidents since 1867. Four new members were elected. The sum of £1358 10*s*. was voted for the half-yearly grants to the annuitants of the charity. Five letters had been received from widows of medical men since the last court asking for relief and this had in each instance to be refused owing to the fact that their husbands had not been members of the society. Mr. Edward J. Blackett was re-elected secretary. The membership of the society is open to any registered medical man who at the time of his election is in practice within a radius of 20 miles from Charing Cross. Full particulars and application forms may be obtained from the secretary, 11, Chandos-treet, Cavendish-square, London, W. The next election is on Oct. 11th, and names of intending candidates must be received on or before Sept. 19th.

full translation of Dr. Lancereaux's remarkable communication will appear in the September number of the *ris Medical Journal*.

May I be allowed to supplement your Paris correspondent's e by pointing out that Dr. Lancereaux has used this thod since 1899, has found it free from danger in an perience of over 1200 injections, and that he has been led consider it as the only method meeting the indications for atment. In this, his latest communication on the subject, . Lancereaux gives full details of three cases of aneurysm of the abdominal aorta, of the first part of the aorta with sternal tumour, and of the ophthalmic artery with robbing exophthalmos—all apparently cured. The injecn, consisting of 200 grammes of a 7 per 1000 saline ution containing five grammes of gelatin, is made into the iteal region every five or six days (being generally comtely absorbed in a few hours), from 30 to 40 being usually quired. Successful cases have been recorded even when skin over the sternum was thinned by the aneurysmal . Such treatment surely holds out more hope than can expected from rest, diet, potassium iodide, &c.

I am, Sirs, yours faithfully,

aris, July 19th, 1906. A. A. WARDEN.

SSOCIATION OF MEDICAL DIPLOMATES OF SCOTLAND.

To the Editors of THE LANCET.

SIRS,—May I ask (through the medium of THE LANCET) se holding Scotch qualifications kindly to reinform me of various disabilities and grievances they may know pertaining to these qualifications, in order that they may investigated and redressed, if possible, by the above ociation.—I am, Sirs, yours faithfully,

CLAUDE ST. AUBYN-FARRER,
, Westbourne Park-road, W., July 16th, 1906. President

THE AFTER-EFFECT OF ETHYL CHLORIDE ANÆSTHESIA.

To the Editors of THE LANCET.

SIRS,—I have followed with interest the reports on ethyl loride as an anæsthetic, especially in dental work. I ve used it for that purpose in a large number of cases and d it a good anæsthetic, as there is a period of analgesia ter the patient is conscious. As yet I have had no fatal ses but have noticed bad after-effects. I always fill the g with nitrous oxide and then gradually drop into e bag from a side tube three cubic centimetres of ethyl loride (for an adult). Dr. A. B. Kingsford in his ports says that he has noticed two forms of rigidities, t according to his experience they come on during e anæsthesia. In all my cases the rigidity was only oticed after the dental operation was past. The local asm I found most frequently in the fingers; the patient omplained of great pain and it took considerable force to elax the same. This form of rigidity occurred very frequently. s to the second form of rigidity the patient took the anæshesia all right and after the teeth were out he suddenly ook what to me looked exceedingly like an epileptic fit. hen he became quite rigid in the opisthotonos position long the dental chair. The pulse could hardly be felt, the reathing ceased for a few seconds, his head was retracted o the one side, the teeth were clenched, and the eyes staring and fixed with the pale grey ash colour of death. He suddenly became conscious and felt sick and vomited, but on trying to get out of the dental chair he had a tendency to become rigid again. His pulse was 39 but it gradually became 53 after a hypodermic injection of one-fortieth of a grain of strychnine. It may be interesting to state that his pupils were unequal for 48 hours after the operation, the right dilated and the left pin-pointed. On examination of his heart the first sound in the mitral area was not heard distinctly but otherwise he seemed in good health. The difficulty I find in using nitrous oxide alone in dental work—and rather to get the patient to sit different times—is that with some patients you cannot get a proper anæsthesia with gas at all. I am strongly of the opinion that there is always great danger in giving ethyl chloride in the sitting posture. I may state that I always prepare my patients for the operation as if I was going to give chloroform. Thanking you in anticipation,

I am, Sirs, yours faithfully,
JOSEPH STARK, L R.C.P. & S. Edin.
Fruitfield, Airdrie, July 23rd, 1906.

THE GENERAL MEDICAL COUNCIL: THE DIRECT REPRESENTATIVE FOR SCOTLAND.

To the Editors of THE LANCET.

SIRS,—We have been instrumental in promoting a requisition to Dr. Norman Walker inviting him to be a candidate for the post of Direct Representative for Scotland on the General Medical Council. Dr. Walker received so large a measure of support on the last occasion and has since continued to take so active and useful a part in the promotion of the improvement of medical education as well as in other matters of medical politics that we have every reason to believe that on this occasion his candidature will be successful.

The requisition has been largely signed by practitioners from all parts of Scotland and Dr. Walker has indicated his willingness to accept it. We shall be glad to hear from those who wish to join the general committee.

We are, Sirs, your faithfully,
G. A GIBSON,
3 Drumsheugh-gardens, Edinburgh.
F. W. N. HAULTAIN,
July 24th, 1906. 12, Charlotte-square, Edinburgh.

A NECESSARY REPUDIATION.

To the Editors of THE LANCET.

SIRS,—My attention has recently been drawn to an article in the *British Medical Journal* of July 14th where, under the column Medico-Legal and Medico-Ethical, reference is made to a weekly paper called the *Free Lance* and to a Dr. A. W. Wheatly advertised in its columns.

On applying at the offices of the General Medical Council I find that I am the only man with those initials and name on the Medical Register. The subject being, as the *British Medical Journal* describes, "Touting for Patients" (and I may add in a very objectionable way), I take this my earliest opportunity of disclaiming any knowledge of the person there described, or connexion of any kind with him or his methods.

Your sense of justice and your knowledge of the injury that may accrue to me from this base use of my name will, I feel sure, enlist your sympathy and help by publishing this my disclaimer in the next issue of THE LANCET.

I am, Sirs, yours faithfully,
ARTHUR W. WHEATLY, M.B.Durh.,
Consulting Surgeon, Western Ophthalmic Hospital.
Kensington, S W., July 24th, 1906.

*** We sympathise warmly with our correspondent, who has a right to feel intensely annoyed with the *Free Lance*.—ED. L.

THE UNIVERSITIES AND THE FUTURE OF DENTISTRY.

To the Editors of THE LANCET.

SIRS,—The progress and development of the profession of dentistry must always be matters of interest to medical men. Whether in the future the two professions will tend to be differentiated more clearly or to become amalgamated completely the aims and objects of the practitioners of medicine and dental surgery are so analogous that any movement on one side will naturally be watched sympathetically by the other. Considerable changes are at the moment taking place in dental education which are likely to have far-reaching effects upon the ultimate development of the profession. With regard to the movement for the establishment of university degrees in dentistry a hope has been very generally expressed that it might be found possible to grant to the members of a learned profession the customary hall-mark of a liberal education. In the practical carrying out of this idea a very distinct division in the views of the teachers of dentistry has been disclosed. While one point of view has been shown to be held by a majority of the teachers in most provincial centres of dental education, an antagonistic view seems very strongly held by an important majority of metropolitan teachers. So distinctly local does the cleavage in the teaching profession seem to be that I may conveniently speak of the two opposing views as the metropolitan and the provincial ideals for the development of the dental profession. The metropolitan ideal appears to be the establishment of dentistry as a special department of medicine on lines analogous to the applied to districts like the Punjab. The experience of the agents of the mission to lepers in all parts of India coincides with that of Mr. Guilford—viz, that cases of leprosy are very few indeed among Indian Protestant Christians and that a converted leper applying for admission to an asylum is a rare event.

The importance of this particular aspect of the general question will be clear when it is added that there are in Indian asylums connected with the Mission to Lepers no fewer than 2700 Christians, at least 95 per cent. of whom were lepers prior to conversion, a fact which must largely modify Mr. Hutchinson's conclusions that they indicate the prevalence of leprosy among Indian Christians

On the general question of the relation between fish-eating and leprosy I offer no opinion. My personal attitude is one of suspended judgment; "not proven" must at present, I think, be the verdict. But however this may be Mr. Hutchinson deserves our gratitude for having elicited many facts which should at least contribute to a solution of this perplexing problem.

I am, Sirs, yours faithfully,
JOHN JACKSON,
Organising Secretary to the Mission to Lepers in India and the East.
Exeter Hall, Strand, London, W C, July 18th, 1906

A CASE OF IDIOSYNCRASY TO EGG ALBUMIN.

To the Editors of THE LANCET.

SIRS,—The following case of extreme idiosyncrasy to egg albumin is, I believe, of considerable rarity and is remarkable from the fact that this substance produces in the patient in question severe gastro-intestinal irritation when taken internally and sets up urticaria when applied locally to the skin.

The patient, a woman, aged 26 years, came under my notice in the early part of this year with the history that from earliest childhood she had been unable to take eggs or to eat any article of diet which contained them. It was stated that the amount of egg required to produce severe symptoms was extremely small, even the minute quantity contained in the glazing of a roll being sufficient to cause considerable uneasiness. The first occasion on which egg was given to her was stated to have been at the age of ten months and nearly resulted in her death, the symptoms consisting of muscular rigidity and cyanosis. Subsequently many attempts were made to establish toleration to eggs but without result. At the present day the patient finds her disability of the greatest inconvenience, as the certainty of becoming ill if she should happen to partake of any dish in the composition of which eggs have been used practically precludes her from dining away from home. The symptoms depend upon the dose of egg which is taken. A quantity equivalent to four grammes would appear to be a relatively large dose and is followed in a short time by stinging in the throat, epigastric pain, vomiting, and later by either diarrhœa or obstinate constipation. With smaller doses pain comes on about an hour after the egg has been taken and lasts a longer or shorter time according to the dose.

In addition to the gastro-intestinal irritation produced by the ingestion of the egg, it was stated to me that the application to the skin of the raw white of egg would raise a blister. Being naturally sceptical of the possibility of this I arranged for an experiment to be made in my consulting room and the result showed beyond a doubt that egg albumin certainly possessed a directly irritating action upon the skin. On April 10th, at 12 o'clock, a little raw white of egg was spread over an area on the forearm of the size of a half-crown. In half an hour's time this area was deeply reddened and presented several raised wheals. I may state that the skin over the whole body was remarkably irritable and dermographic. The organs of the body were sound, there was no albumin in the urine, and no signs of gastro intestinal disturbance. As the patient had consulted me with the hope of finding some means of cure, or at least of alleviation, I suggested that vegetable charcoal might possibly be found to act as an antidote. My suggestion has been acted upon with apparent success. The patient writes that, having accidentally taken some egg in soup, which judging from previous experience would certainly have brought on an attack, she took at once a charcoal pastille, with the result that no unpleasant effects were experienced. Experiments are now proceeding with the object of ascertaining the exact amount of egg albumin which is neutralised by a given weight of charcoal.

I am, Sirs, yours faithfully,
GEORGE HERSCHELL, M.D. Lond.,
Senior Physician to the Kensington General Hospital.
Harley street, W., July 21st, 1906.

STUTTERING.

To the Editors of THE LANCET.

SIRS,—The lack of any reference to spirometric readings in the lecture by Dr W. S. Colman on Stuttering published in THE LANCET of July 14th, p. 70, strikes me as a very noticeable feature. I have made some observations in cases of stuttering and every case I came across was below the proportional chest build. The chest was not well developed and the respiratory capacity, as tested by a spirometer, was considerably below the normal—in other words, the pump supplying the voice reed was inadequate. The breathing capacity is always increased by encouraging the development of abdominal breathing, which is so well marked in good singers, but is discouraged by the writer of the article who observes "that singing relieves the stuttering" and calls it a "trick." The explanation is simply that the words of the song and the time of the tune unconsciously give the singer an idea of the quantity of air required to phonate, and it is this idea that requires cultivation in order to relieve stutterers of their impediment.

I am, Sirs, yours faithfully,
Swansea, July 17th, 1906 G. ARBOUR STEPHENS.

THE TREATMENT OF RINGWORM.

To the Editors of THE LANCET.

SIRS,—I have read with interest the various articles and letters which have appeared in THE LANCET on ringworm and I have been struck with the ease with which some men can cure it with comparatively simple remedies. My experience unfortunately has been quite the reverse. In deep-seated ringworm parasiticides and escharotics I have found of little or no practical utility. It would take up too much space to enumerate all the drugs I have tried for months without success. About a year ago, however, an article by Dr. H. G. Adamson appeared in THE LANCET on the Treatment of Ringworm of the Scalp by Means of the X Rays,[1] and I asked Mr. Blackburn of Messrs. Mottershead and Co. to carry it out according to the directions on several cases which had resisted all treatment for months. This he did, measuring the rays with pastilles, which necessitated an exposure of from 20 to 24 minutes for a single sitting for each patch. Some of the children had it applied three or four times for different patches at intervals of several days. Their heads were then anointed with a weak ammoniated mercury ointment. In three weeks the hair came out, leaving a bald patch which in the course of a few months became covered with hair free from ringworm. To my mind x-ray treatment when it can be obtained is the most satisfactory means yet devised for the cure of ringworm.

I am, Sirs, yours faithfully,
J. W. STENHOUSE, M.B. Edin., M.R.C.S. Eng.,
Medical Officer, Royal Deaf Schools, Old Trafford.
July 2nd, 1906.

DR. LANCEREAUX'S METHOD IN THE TREATMENT OF ANEURYSM.

To the Editors of THE LANCET.

SIRS,—Many of your readers will have noted with interest your review of "Heart Disease and Aneurysm of the Aorta," by Sir William H. Broadbent and Dr. John F. H. Broadbent, on p. 94 of THE LANCET of July 14th. Although dealing especially with treatment these authors offer little encouragement as regards the use of the one important therapeutic measure introduced in the last few years in the treatment of aneurysm—namely, the subcutaneous injection of gelatinised salt solution. As your reviewer remarks, "their condemnation of this means of treatment is rather too sweeping." May I call the attention of your readers to Dr. Lancereaux's communication to the Academy of Medicine on this subject, briefly summarised in the same number of THE LANCET (July 14th) by your able Paris correspondent.

---

[1] THE LANCET, June 24th, 1905, p 1715.

Specialists, as we now have them, are mostly limited practitioners with a hospital appointment. The hospital appointment, probably well deserved, is a good advertisement, for it brings the men and their names prominently before the public and gives them opportunities for practice and for self-advertisement which are not possessed by the men who fail to get such appointments. The staff of a hospital is necessarily limited. The men already on it have a power which they can use, on occasion, for the benefit of a friend or a favourite. Of two young men equally well qualified and both ambitious to secure a vacant post the one who is looked upon by a member of the staff with friendly regard as well as respected for his ability and attainments is more likely to secure the majority of votes than the one who has merely first-rate qualifications and testimonials, for boards of management are always (or usually) open to the advice of the professional members and readily accept the dictum of the man who has won their confidence either by plausibility or by good work.

Now I do not blame either the board or the interested and friendly advocate. Most of us probably when seeking an appointment much to be desired would gladly avail ourselves of such powerful help and the man who is successful in his application may be justly congratulated. But the man who fails may be equally deserving, and his failure, as things go now, may profoundly and adversely affect his subsequent career. Often a young man, qualified by years of patient toil, both at books and at the bedside; nay, who is already the occupant, perhaps, of a minor post in a hospital, has his prospects blighted and his heart discouraged by an unwarranted and partisan preference for a competitor, whose qualification, judged solely with regard to merit, is much inferior to his own. I know of such a case and therefore can write with authority and, doubtless, a similar knowledge belongs to many others in the profession. What, then, should hinder this young man from doing that which would give him the next best chance of pursuing with success the career upon which he has set his heart? What harm can there be? what moral or legal obligation would be disregarded, should he set himself forward, to his friends and to others, as a man desirous of following a special line of medical or surgical practice? Already his friends know of his special preparatory work and of his proclaimed, and perhaps acclaimed, intention. Why should he have to sink into the whirlpool of competitive general practice just because, through no fault or deficiency on his part, he has failed to obtain an entrance ticket, as it were, to a *quasi* close corporation, whose justification for existence has no better foundation than that of the private opinion of its jealous members? I can see neither wrong nor harm in the thing that I suggest. A medical man may, with the consent of all, call himself "surgeon" or "physician." What wrong can there be in adding to the name a descriptive phrase to indicate the special branch he wishes to pursue? The supposed objection would seem to be ridiculous and I for one, until a sounder reason than any I know of be brought forward, must refuse to accept it. And if, then, a young man, qualified by the schools and the hospitals, may claim this privilege, what should hinder the claim of an old man, qualified by a life's experience in addition to the other?

Will you, Sirs, or will any others tell me if I am wrong, and show me the fallacy of my argument? or, failing to do that, will you or they give me the advantage of your or their support?

I am, Sirs, yours faithfully,

A. Z.

⁂ "A. Z.'s" excellent letter contains amidst its plenitude of truth some faults in argument—at least, that is our view. To comment upon the letter at once might be to stifle the discussion which he seeks, and which would, we think, be valuable. We should like to hear other professional opinions. —ED. L.

THE MEAT OF THE PEOPLE.

To the Editors of THE LANCET.

SIRS,—Your annotation in THE LANCET of July 14th on "The Meat of the People" is well timed and well worthy of the serious consideration of all who are interested in the physical well-being of the race. I have had opportunities within the last few years of studying the question somewhat fully and the conclusion I have arrived at is that, however savoury well-cooked foreign meat may be, its nutritional value is very low in proportion to the price charged for it, especially when it is palmed off on the public, as it unquestionably frequently is, as fresh English meat.

I have seen in different parts of New Zealand the whole process of preparation of mutton and lamb for the English market and I have nothing but admiration for the eager watchfulness and care with which the process is carried out in that colony. Here there is no question of suspicion as to cleanliness or purity or careless inspection. It is a question of comparative nutritive value of the meat when placed on the table.

I venture, in the first place, to doubt whether the quality of the mutton when fresh is equal to that of home-fed mutton. I know that much of the grass is grown from English seed. But it has not the same appearance as English grass. It looks ranker and coarser, as if it had grown to quantity rather than quality and to be deficient in chlorophyll, whatever that may imply.

Secondly, and of this I am convinced, the freezing process of itself greatly diminishes the nutritive value of the meat and renders its fibre less digestible. Whether this process acts in this way continuously during the long period of transit to this country I am unable to say, but I think it is quite possible.

Thirdly, I believe the further diminution in nutritive value during the process of thawing to be enormous and that this process is not properly understood and seldom properly carried out.

Lastly, it is well known that even the best home-bred and fed mutton loses considerably and inevitably in nutritional value in the process of cooking, however skilfully this may be performed. I think that in the case of meat which has been frozen, perhaps for months, and thawed in a few hours the nutritional loss sustained in the cooking process is likely to be proportionately much greater.

I therefore believe that by the time the meat reaches the table its value as nutriment is low as compared with that of fresh English mutton and does not represent the value at which it is sold.

It is all very well to be told, as we so often are, that when placed on the table well cooked you cannot tell New Zealand from English mutton and that some people prefer it to English mutton. This does not affect the difference between the two as nutriment; and it is only true when the joints are hot.

As I believe the New Zealand mutton and lamb is the best and the most carefully supervised form in which our imported meat-supply arrives I will not touch upon the other sources. But I think it should be regarded as a very serious offence when consumers are charged the value of fresh English mutton for what is, I believe, a far less wholesome and less nutritious article.

I am, Sirs, yours faithfully,

PERIPATETICUS.

PROFESSOR AUGUST FOREL ON THE SEXUAL PROBLEM.

(FROM A CORRESPONDENT.)

THE Hungarian National Defence League against the spread of sexual diseases, conjointly with the "Good Templar" Order, recently held a meeting of considerable interest in Budapest.

Professor August Forel was invited to deliver an address and to enlighten the public on the hygiene and ethics of sexual life. In Hungary, where syphilis and other venereal diseases cause immense harm and distress, the medical profession welcomes every movement which may have the effect of diminishing this scourge. The town-hall, where the address was delivered, was crowded with people of all ranks and occupations who paid the greatest attention to all that was said.

Professor Forel was introduced by Dr. Leo Liebermann, professor of hygiene and public health at the University of Budapest. In the early part of his address he explained the idea of ethics. He endeavoured to prove the evolution of ethical feelings on a natural basis, tracing them back to the remote period when the instinct of preservation of the species formed the only link between human beings. The field within which affection might exist at first included only individual males and females but it was gradually enlarged until it position at present occupied by ophthalmology or laryngology, whilst in the provinces the aim of the teachers is rather the development of an independent or sister profession working hand in hand with medicine but under a separate organisation and having an educational curriculum planned to meet its own special needs. In their attitude towards the proposals that have been made by various universities with regard to the regulations for degrees in dentistry the two parties have very clearly indicated the hopes which they entertain for the future of the profession. In London the majority of teachers have expressed the opinion that no degree in dentistry should be conferred on any person who does not already possess a university degree qualifying him to practise medicine and surgery. Several provincial universities have, on the other hand, already established degrees in dentistry, the regulations for which merely require that candidates shall have worked out a more elaborate curriculum and have attained a higher standard of knowledge of their own special subjects than those hitherto demanded of candidates for a licence in dental surgery. It does not appear that the University of London has yet decided whether to fall in with the wishes of the majority of metropolitan teachers or to follow the example of the provincial universities which have already instituted independent degrees. It is, indeed, not quite clear whether the University would best meet the wishes of metropolitan teachers of dentistry by offering a special dental degree to its medical graduates or by withholding a degree in dentistry altogether.

To withhold degrees altogether would obviously be the best means to secure that in the University dental surgery should be treated on the same footing as any other special branch of medicine or surgery. But whether this course is pursued or whether special degrees in dentistry are offered to medical graduates, or whether the degree of Master of Surgery is modified so as to be adapted to the requirements of surgeons wishing to show special knowledge of dentistry, the University of London in thus supporting the metropolitan ideal of dental development may inflict a serious blow to dental education in London, as well as to the best interests of the dental profession and of the public. The attempt to secure that the practice of dentistry should be confined to the members of the medical profession is one upon which the medical profession is justified in having a very strong opinion, and I am sure that my views are shared by many. If the ideal of some that all dentists should be fully qualified medical men ever had any prospect of fulfilment it was entirely shattered, I think, by the passing of the Dental Act. Some progress towards the absorption of the dental into the medical profession has hitherto been possible, because the taking of diplomas or degrees in medicine has hitherto been the only method of satisfying the ambition of a dental student who felt that a mere licence in dental surgery allowed him insufficient scope for showing his determination to rise to the higher ranks in his profession. This means of satisfying his ambition has been encouraged by the Royal Colleges and by the medical schools, and has been undoubtedly successful in helping dentists, who become also qualified medical practitioners, to secure appointments at hospitals, the recommendations for which are generally made by the medical staff. These proceedings have been watched by some interested in dental education with complacency and by others with much anxiety. The medical curriculum can hardly be regarded as an ideal education either of mind or hand for those who do not wish to practise medicine; and many have insisted that to require a dentist to be also educated as a doctor of medicine is not more certain to make him a better dentist than if he were required to be educated also as a doctor of divinity or of music. The education of those dentists, whose ambition leads them to qualify also as medical men, must be crowded and cramped, while there is risk that the curriculum for all dentists may be badly arranged because it may be dominated by the ideas of those who wish to make it easy for a dental student at any time to become also a medical student. Another serious result of this policy of amalgamation has been the constant "bleeding" of the dental profession of its best material. It is only the students of good preliminary education and keen enthusiasm who can face the hard work and strain of securing a medical as well as a dental qualification. It is stated by those thoroughly conversant with the facts that a large proportion of these best dental students so soon as they are qualified desert dentistry and practise either medicine or surgery.

In considering this important question it must not be forgotten that a qualified medical practitioner has conferred upon him by the Dental Act all the rights and privileges of a qualified dental surgeon. The attempt therefore to amalgamate the professions practically amounts to an attempt to eliminate the specially qualified dental surgeon. To many it appears that its ultimate result would be to throw back the practice of dentistry into the hands of the barbers and unqualified and uneducated persons who performed these duties for the public before the Dental Act was passed. To me it seems inconceivable that a sufficient supply of dentists to deal with the immense public need should ever be admitted through the portal of the medical profession, although I know that many, and probably you, Sirs, hold the opposite view. But the action of the provincial universities has removed the lever which the metropolitan idealist hitherto possessed for the promotion of this view. The ambitious student can now seek a university degree in dentistry in addition to his dental diploma, confident that the extra training to which he will be required to submit will improve his capacity either as a practitioner of dentistry or as a reseacher in the departments of dental therapeutics or pathology. If he cannot secure such a degree in the university of his own city he will seek it elsewhere. It seems probable, therefore, that those cities the universities of which refuse to recognise special dental attainments unless they are accompanied by the technical knowledge required of a qualified medical practitioner, will be seriously handicapped in their attempt to maintain efficient schools of dentistry.

I am, Sirs, yours faithfully,
A London Physician and Teacher.

TWO POINTS OF MEDICAL ETHICS.

To the Editors of The Lancet.

Sirs,—I have the honour to write to you to ask for a decision on two points of medical ethics which refer chiefly to medical officers in military employ attached to regiments.

1. When a regimental officer reports sick with some disease such as gonorrhœa, scabies, or acute alcoholism, to which, rightly or not, a certain amount of shame attaches, what should be the medical officer's procedure as regards his daily report of sick to his commanding officer, such sick report being a printed form with a space for the names and diseases of sick officers and being in no way a confidential report? Besides being seen by the commanding officer, it is seen by numerous clerks, sergeants, and officers, hence the question arises on which I ask a decision—viz., What is one's duty considering both one's duty as a medical officer to the officer commanding (who writes the regimental officers' annual confidential report) and one's duty as his doctor to the patient?

2. The other point on which I ask your opinion is as follows. All regimental officers are, of course, entitled to the services of their medical officer. A case occurs in which a medical officer is attending a regimental officer for illness, the regimental officer, without informing his medical officer, goes to see another medical man (not connected with the service) who attends the officer for two or three days; the officer then deciding to revert as a patient to his own medical officer, sends for him, maintaining he (the regimental officer) has a right to any services he may call for. The medical officer, after protesting against the professional indignity to which he had been submitted, continues to treat the regimental officer. A few months later the same officer again falls ill and again behaves in an exactly similar manner and the medical officer cannot, according to regulations, refuse to attend the regimental officer in future. What should he do? I inclose my card.

I am, Sirs, yours faithfully,
I.M.S.

June 1st, 1906.

WHAT IS A SPECIALIST?

To the Editors of The Lancet.

Sirs,—A little while ago I wrote to you virtually asking this question: Can any medical man, especially an old man, if he chooses to practise as a specialist, call himself such on his door-plate? You courteously replied in the negative but with your permission I would like to enlarge my plea, *as follows:*—

or on behalf of, patients towards their own maintenance amounted to £1606. The special donations received during the year were as follows: Hospital Sunday and Saturday Fund, £368 15*s.*; Mr. Arthur Earle, £300, "In Memoriam Elizabeth Earle"; whilst other special donations amounted to £165 10*s.* The expenditure incurred in laying out the fields is now fully justified by the improvement in the general appearance of the grounds and also in affording increased facilities to patients for open-air exercise. The fourth closed shelter completed this year has proved an additional attraction for patients.

July 24th.

WALES AND WESTERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENTS.)

Cardiff and Swansea Hospitals.

THE complete report of the Cardiff Infirmary for the year 1905 shows that the economical management which has characterised this institution in former years has been maintained. The average weekly cost per patient was £1 4*s.* 8*d.*, or about 3*d.* per week less than in 1904. The average cost per occupied bed was £64 5*s.* 4*d.*, a sum which compares favourably with that expended in the Swansea Hospital during the year ending May 31st last—namely, £71 19*s.* It is only fair to state that the cost per bed in Swansea in the previous year was only £63 12*s.*, and the total income in the year just ended fell short of the total expenditure by only £183, whereas the Cardiff expenditure exceeded the income by £2312. The more favourable financial position of the Swansea institution appears to be almost entirely due to the larger proportionate amount contributed by the workpeople of the district as compared with Cardiff. The total income in Swansea was £8265 and the workpeople subscribed £3519, or 42 per cent. In Cardiff the total income was £11.725 and the workpeople's contribution was £3584, or 30 per cent. of the whole. If the Cardiff workpeople had contributed in the same proportion as their comrades in Swansea there would have been a balance on the right side of nearly £100 on the year's working of the Cardiff institution. Although a great deal has been done during the past few years in the way of remodelling the wards and the administrative quarters of the Cardiff Infirmary nothing has been done to improve the out-patient department with the exception of the erection of casualty rooms. It is estimated that a sum of £7000 should be spent on this department if it is to fulfil the requirements of the present day. Early in the year an anonymous donor offered £1000 towards this amount, provided the remainder were forthcoming from other sources before the end of the year. It is gratifying to find that there are now only £2000 to be subscribed towards the sum named.

Infantile Mortality in Cardiff, Swansea, and Rhondda.

The statistical table relating to infantile mortality which is now included in the annual reports of medical officers of health enables a detailed comparison to be made of the number of deaths of young children in different localities. In 1905 the infantile mortality rate in Cardiff was 118 per 1000 births, in Swansea 130 per 1000, and in the Rhondda 199 per 1000. The Rhondda rate was about equal to that which has been recorded during the previous ten years and was higher than that in any of the 75 great towns of England and Wales. It is of interest to find that the proportion of deaths at varying age periods was practically the same in the three towns. In Cardiff 27 per cent. of the children died under a month old, in Swansea 28 per cent., and in the Rhondda 26 per cent. Under six months old there died in Cardiff 68 per cent., in Swansea 71 per cent., and in the Rhondda 68 per cent. When the causes of death are compared there is, however, a much greater disparity. Premature birth was recorded as the cause of death in 12 per cent. of the Cardiff children, in 10 per cent. of those in Swansea, and in only 7 per cent. of those in the Rhondda. Tuberculous diseases were responsible for 6 per cent. of the Cardiff deaths, 4 per cent. of those in Swansea, and 3 per cent. of those in the Rhondda. Diarrhœal diseases caused 14 per cent. of the Cardiff, 10 per cent. of the Swansea, and 20 per cent. of the Rhondda deaths. In connexion with this last group Dr. J. D. Jenkins states that no measures directed specially towards their prevention have been carried out in the Rhondda with the exception of the distribution, through the medium of one of the registrars of deaths, of cards containing a number of hints drawn up both in English and in Welsh for the guidance of mothers in the feeding and general management of their babies. This distribution has been going on for four years and it is now possible to compare the diarrhœal death-rate during those years with that which prevailed previously. As the cards were distributed in only a portion of the district and to the mothers of four-fifths (about 3600) of the children born in the whole of the Rhondda it is also possible to compare the results during the same years in the card-distributed area with those in the district where no cards were given. In 1905 the infantile diarrhœa death-rate was 33 per 1000 births in the "card district" and 50 per 1000 in the rest of the sanitary area, compared with 74 and 58 respectively in 1901 when no cards were distributed. The fall in the "card district" is thus very noticeable. It should be stated that the division of the two districts is a purely arbitrary one. The inhabitants of each are of the same class of life, living in similarly built houses the sanitary arrangements of which are almost identical and with the wage-earner bringing home about the same amount of money. These results as recorded by Dr. Jenkins are a strong argument in favour of his plea for the appointment of one or more women inspectors who by visiting the homes of the people could point out the pitfalls to be avoided and the best measures to adopt in order to assist in the upbringing of healthy and well-grown children.

The Dolgelly Urban Council and Isolation.

The question of providing an isolation hospital for the urban and rural districts of Dolgelly, in North Wales, was further discussed at meetings of the urban and rural councils held on July 20th and 21st. Since the previous meetings of these councils, mentioned in THE LANCET of June 23rd, p. 1791, there have been 16 fresh cases of scarlet fever notified in the urban district and one death occurred in a small cottage where there were four cases of the disease and where any kind of isolation was impracticable. Two deputations, representing the district nursing association and Dr. Williams's Endowed School for Girls, attended before the urban council and urged it to proceed with the erection of an isolation hospital, a free gift of land for which purpose has been offered. A petition to the same effect, signed by 300 residents, was also handed in. Reference was made to the pecuniary loss caused by the outbreak of infectious disease in towns that laid themselves out as visitors' resorts like Dolgelly, and on behalf of the school it was pointed out that they would be incurring a great danger if it was rendered unsafe for the boarders from various parts of England and Wales to be together with the day pupils from the district. At a previous meeting of the rural council it was decided to accept the offer of a free gift of land and to proceed with the erection of a hospital at a cost not exceeding £500, provided that the urban council contributed two-thirds of the cost, the rural council to contribute one-third. The urban council after a discussion lasting for two hours accepted those terms but only on the casting vote of the chairman. The rural council met the following morning and after further considering the matter decided to take no further action until the views of the various parishes were obtained. It was stated that 90 per cent. of the rural population were opposed to the movement as it would increase the burden of the rates.

Monmouthshire Water-supply.

The example set by the county council of Glamorgan in its endeavour to secure for the inhabitants the county watersheds is being followed by the Monmouthshire council. The county surveyor has presented a report dealing with the available supplies in the county and at a conference held on July 18th between representatives of the council and of the local sanitary authorities a proposition was unanimously passed expressing the opinion that it was desirable to conserve the present sources of water-supply and to take steps to prevent outside companies and bodies from extracting water to which the inhabitants of the county have a natural claim. The county council was asked to promote a Bill in the next session of Parliament having these ends in view. Monmouthshire has an area about two-thirds that of Glamorgan and a population in the administrative county of only about one-third, but a very large extent of the Monmouthshire coalfields is still unworked, so that a great increase in the population is probable during the next 20 years when the eastern and western valleys of Monmouthshire will be as densely populated as included families and culminated in the true ethics of humanity, the modern sentiment of love uniting the whole human race. It was a generally accepted opinion that family affection was a distinctively human characteristic but this he considered to be no more than an exhibition of human self-conceit. The lower animals showed obvious examples of family affection and among them parrots, monkeys, and swallows stood on the highest pinnacle of domestic faithfulness.

Professor Forel then went on to say that in the human species it was altogether at variance with ethical principles that the male sex should make use of its superior strength to oppress the female sex. Only education could help in developing the ethical feelings—that education which taught men to keep their lower instincts in check. Temperance in appeasing every need was not by any means the same thing as leading an ascetic life. The greatest difficulty of ethical life was that the results of deeds inspired by ethical feelings were not in harmony and in proportion with the intention. Therefore the art of real ethical education consisted in making motives and deeds harmonise. Professor Forel declared egotism to be an anti-ethical feeling according to the actually accepted sense but he emphasised the fact that in their true sense egotism and altruism were not opposed to one another and that both were necessary. He said that laws were necessary evils; they were, however, indispensable for keeping our passionate inclinations in check. These inclinations we inherited with our nature. The more evolved and developed mankind became the less need there was of laws.

Speaking of sexual ethics, Professor Forel alluded to the Malthusian system, which experience had proved to be impracticable and, in fact, it could not be otherwise, for it did not take account of human nature and was simply a propaganda of abstinence. He rejected also the views advocated by Tolstoy who began to proclaim the benefits of continence at an age when, owing to his advanced years, he was already beyond temptation. The artificial prevention of conception was, however, an ethical duty in all cases in which the woman could not regain her strength after her first labour and in which married couples were the subject of bodily or mental deficiency. Professor Forel did not recommend the prohibition of child-bearing but only its regulation. Healthy, intelligent women ought, he said, to bring forth many children at proper intervals. He vehemently denounced the social injustice with which illegitimate children were treated and he demanded for them an entire equality of rights. He also spoke very severely of the terrible negligence which allowed girls to enter the state of matrimony without having previously been enlightened. He sharply criticised the existing system of prostitution and the so-called *mariages de convenance* and said that only stupidity could prevent the enlightenment of children in sexual matters.

Coming to the hygiene of sexual life Professor Forel demonstrated that ethics were here in complete agreement with hygienic laws. Everything that the ethics of sexual life claimed was at the same time hygienic. He referred to the dangers of alcohol, which were well shown by the fact that most insane people and bodily and mentally deficient children were descended from intemperate parents. Such children have usually been conceived after the consumption of alcoholic beverages. The State organisation of prostitution did not deter young men from resorting to prostitutes and rather had the effect of inducing them to do so. It therefore ought to be discontinued and marriage ought to be encouraged among young men. Men ought not to defer marriage until they had earned enough to live luxuriously and to give parties and entertainments but they ought to marry while they could love their wives with the fervour of early manhood.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

The Report of the Medical Officer of Health for 1905.

Dr. E. W. Hope's report on the health of Liverpool during the year 1905 possesses many points of great interest. Dealing with the large amount of infantile mortality, he states that the loss of infant life in the various districts of the city varied widely, the range during the year being from 84 per 1000 in the district where it was the lowest up to 240 per 1000 in the district where it was the highest. Even in the lowest the death-rate of infants was more than four times as high as the general death-rate of the community. Zymotic diseases accounted for 899 deaths, the great majority of them—viz, 681—being due to diarrhœa, the exciting cause being, no doubt, the same as that in the case of atrophy—viz, improper feeding. Following upon this comes whooping-cough with 60 death and measles with 59 deaths. Under the heading of diseases of the digestive system no less than 267 deaths of infants are recorded; 677 deaths of infants were due to diseases of the respiratory system and 496 deaths to diseases of the nervous system. The natural guardian of the infant is the mother and it is only with extreme caution that the efforts of the municipality can be specially directed to the preservation of infant life, but such efforts have been made in a variety of ways. Hospital provision is now available for infants suffering from whooping-cough and measles where they can be received, together with the mother if necessary. With regard to feeding there is strong evidence that the efforts of the health committee in widely circulating instructions as to the feeding of infants, in employing a large staff to give verbal instructions and to supervise, in establishing sterilised milk depôts at which milk specially prepared for infants can be obtained, and in improving the general sanitation of slums have resulted in marked benefit. Dr. Hope alludes to the good results which have followed from the voluntary notification of cases of pulmonary tuberculosis since February, 1901, when the system came into operation. A special form upon which the notification can be made has been circulated among medical men and in those cases in which the requirements of the health committee have been fulfilled the usual notification fee has been paid. During the year 1905, 1971 cases of pulmonary tuberculosis were reported, of which 110 were duplicates, leaving a total of 1861 cases reported. The deaths from the disease totalled 1245; in 614 instances the rooms and bedding were disinfected and in 64 cases the bedding, &c., were removed for special disinfection in the apparatus for that purpose. Out of the 1861 cases reported 1257 were males. The birth-rate of Liverpool is still the highest in the country, thus raising uniformly the crude death-rate. The death-rate, 19·2 per 1000, was at a point indicative of great health improvement—the lowest ever recorded. Last year six importations of small-pox had to be dealt with—isolation, revaccination, disinfection, and domiciliary visitation for defined periods being among the expedients for the protection of others. There were 325 cases of typhoid fever reported during the year, as against 434 in the preceding year, and 681 in 1903. The deaths from the disease were 49, being 33 fewer than in the preceding year. Those figures represent the lowest recorded since the extension of the city boundaries in 1895.

The Royal Infirmary and Summer Diarrhœa in Children.

The committee of the Royal Infirmary has fallen in with the wishes of the corporation to set apart a ward in the infirmary for the exclusive treatment of children suffering from summer diarrhœa. A ward containing 20 beds has been fully equipped for the purpose in the large recreation room, the expenses of which will be borne by the municipality. It will be interesting to ascertain the causes of the diarrhœa in infants now so prevalent in Liverpool, and every endeavour has been made by the health authorities of the city to cope with the disease. The ward will be in use during the present epidemic.

Liverpool Convalescent Institution.

The Lord Mayor of Liverpool presided over the thirty-second annual meeting of the subscribers in the Gladstone Hall of the institution, at Woolton, on July 14th. The report of the council shows that 2732 patients were admitted during the year 1905. The increase in the number of patients is to a large extent the result of the system of nomination and recommendation forms, by which subscribers and donors are entitled to recommend patients for admission, either on payment of the nominal sum of 5*s*. per week, or without charge, in proportion to the amount of their contribution. By this coöperative system benefactors are brought into more intimate touch with the working and administration of the institution and their interest is maintained. By the liberality of Miss Winslow and Messrs. Walker of Litherland, two more free beds have been added, making, with the sums received from new subscribers, a net increase during the year of £65 in annual subscriptions, the total amount under this head being now £1122. The sums received from to the trying time through which Mr. Darnell had passed[1] and to the universal sympathy felt for him by his medical brethren, called upon Dr. W. Calwell (President of the Ulster Medical Society) who conveyed to Mr. Darnell the deep and warm sympathy, not only of the members of his society, but also of numerous medical men throughout the United Kingdom, who had joined in that presentation. He claimed for Mr. Darnell that he had "exercised a reasonable degree of care and skill"; also honesty of purpose and uprightness of conduct, which seemed to his professional brethren to entitle him to a verdict. It was only the absolutely prohibitive expense that prevented the case from being carried to the House of Lords. Dr. Cecil E Shaw (secretary to the Ulster branch of the British Medical Association) read the address, to which Mr. Darnell having replied, the chairman made the presentation. A vote of thanks to the chairman, moved by Dr. John Campbell, terminated the proceedings. Letters of apology were read from the following subscribers to the presentation who were unable to be present: Sir William Whitla, Professor J. W. Byers, Mr. J G. Jefferson (Lisburn), Dr. J. M. Killen (Larne), Mr. J. Rowan (Gargary), Mr. H Buchanan Murray, Dr. Cathcart, Dr. J. S. Morrow, Mr. T. C. Nelson, and Mr. H. T. A. Warnock (Donegal).

Bangor Nursing Society.

At the annual meeting of the Bangor Nursing Society held on July 19th, the Dowager Marchioness of Dufferin presiding, Professor Byers gave an address on Infantile Mortality and Consumption, pointing out the aid which nursing societies might give in the solution of such pressing health problems. At the conclusion of the address Lady Dufferin expressed her appreciation of Professor Byers's address and her thanks to him for coming to Bangor to help their nursing association.

Visitation of the Royal University of Ireland.

Sir William Anson, Bart., M.P., and the Right Hon. Sir A. M. Porter, Bart., Master of the Rolls, held in Dublin, by command of the King, a special visitation of the Royal University of Ireland on July 20th for the purpose of inquiring into the relations between the University and the Queen's Colleges, and to solve the doubt which had arisen as to the meaning to be applied to certain words in the Act of Parliament as to the holding of prizes, scholarships, exhibitions, or Fellowships, or other emoluments by students of the University. The object of the visitation was to determine a legal point raised in the University which affected a number of the students in the three Queen's Colleges of Belfast, Cork, and Galway. It depended on the proper construction of the University Education (Ireland) Act (1879), Section 9, Subsection 4, which provides that "no student holding any exhibition, scholarship, fellowship, or other similar prize in any other university, or in any college attached to a university, or in any college endowed with public money, shall hold any of the said exhibitions, scholarships, fellowships, or other prizes in the university, to be created by the said charter, without taking the value of such previous exhibition, scholarship, fellowship, or other similar prize into account." By some it was argued that under this section a student who obtained a scholarship of, say, £20 value, at any of the Queen's Colleges and within the 12 months gained an exhibition of £40 in the Royal University, will only be entitled to receive the difference between the two amounts from the Royal University as "the value of the previous scholarship must be taken into account." On the other hand, it was argued that having once received the emoluments connected with the Queen's College scholarship the student had ceased to hold it, and did not come under the operation of the statute. If the first view had been established the holders of the many valuable scholarships in connexion with the Queen's Colleges of Belfast, Cork, and Galway would have been disentitled during the year after winning such to obtain money prizes in the Royal University without deduction, or might even receive nothing in some cases. It also meant, what was admittedly unfair, that scholarships provided by private individuals in the Queen's Colleges—who wished to encourage education—should be treated as if they were scholarships founded by public money. It was contended that it was unfair that the amount of one of these scholarships awarded to a student should be appropriated by the Royal University in the event of that student passing an examination and gaining a scholarship in the Royal University. It was, on the one hand, contended on behalf of University College, Dublin, which it was said had no public endowment, that the proper construction of Subsection 4 was one that would prevent concurrent endowments. On the other hand, it was shown that University College had 15 professors, each receiving £400 a year salary and £6000 for its arts course from the Government, whereas the arts endowment to each of the Queen's Colleges was £2638 a year and all the time University College was entirely free from all the exemptions proposed to be put in force in the case of the Queen's Colleges, while in reality it was a Government endowed College. The visitors decided (and against their decision there is no appeal) that a Queen's College student was not disqualified from holding an exhibition in the Royal University because he holds a Queen's College prize. The matter has from time to time occasioned discussions in the Senate and has aroused much unpleasant feeling among the representatives of the institutions concerned; it is therefore hoped that after this authoritative and final decision the matter will be allowed to drop.

July 24th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Malaria and Yellow Fever in Senegal.

ON July 10th M. Kermorgan read a paper before the Academy of Medicine in which he related the good results obtained by the Dakar and St. Louis Railway Company in its efforts to protect its servants against malaria and yellow fever. The improvement in the morbidity conditions was remarkable. At St Louis for the year 1902-03, before the protection of buildings by metallic gauze shutters, ten railway servants spent 139 days in hospital and were also off work for 44 days. In the year 1904-05, after the instalment of such shutters, the number of days in hospital fell to 13, while the men who were off work without going to hospital numbered only two who were off work for 13 days between them. Similar figures were reported from other stations.

Serious Insanitary Conditions in Madagascar.

At the same meeting of the same society Professor. Blanchard gave a most serious account of the widespread and fatal prevalence of malaria in Madagascar. Tananarivo is considered the most healthy place in the island on account of its elevated situation. In 1900 the number of deaths from malaria was 48, in 1903 it was 137, in 1904 the number was 277, in 1905 it had risen to 686, and for the first four months alone of 1906 the deaths had mounted to 980. The population of the town is only 40,000. Professor Blanchard had studied the causes of the outbreak with great care and he had arrived at the conclusion that the primary cause lay in the works for the construction of a road and a railway from Tananarivo to the coast. These works have been the cause of bringing down the Hovas from the healthy plateaux which they formerly inhabited, and where they have up to now been free from malaria, to the low-lying coast lands Here there are two important species of mosquito—pyretophorus costalis and myzomyia funestis—which are carriers of the malaria parasite. As the railway and road are pushed further into the interior the mosquitoes travel with the gangs of navvies and as a consequence the fever also. A similar phenomenon has been observed in Mexico where yellow fever, which was formerly confined to Vera Cruz, crept along stage by stage to the city of Mexico when the railway which unites the two towns was laid down. In the case of Madagascar it is to be hoped that measures of destruction will be taken against the mosquitoes and also that the use of quinine will be insisted upon, for these two methods are the best for combating the malaria scourge.

A New Chair in the University of Paris.

On the motion of M. Roussel the Municipal Council of Paris has just decided to recommend the creation in the Faculty of Medicine of a chair of oto rhino-laryngology.

A Case of Bubonic Plague.

On July 3rd a sailor at Havre was suddenly attacked by acute colic and nausea and being unable to work went home. In the evening of the same day, as he had become worse, a medical man was sent for who prescribed a certain course of treatment. Next day a hospital physician was called in and saw the patient twice. At his second visit he was able definitely to ascertain the presence of enlarged glands in the patient's groin and that also he showed other symptoms of the Rhondda and Aberdare valleys in Glamorgan are at the present time.

Physical Degeneration Posters in Bath.

The health committee of the corporation of Bath has instructed the medical officer of health (Dr. W. H. Symons) to draw up a poster setting out the extent to which physical deterioration is due to the excessive use of alcohol.

July 23rd.

SCOTLAND.

(From our own Correspondents.)

The Notification of Pulmonary Tuberculosis and Measles in Edinburgh.

At a meeting of the public health committee of the Edinburgh town council held this week it was agreed to recommend to the town council that the compulsory notification of pulmonary tuberculosis should be adopted. It was also agreed to recommend the voluntary notification of the first case of measles occurring in a family within a period of two months—that is to say, that after the lapse of two months a case occurring is to be reckoned a first case. At the same meeting it was intimated that since the opening of the wards in the city hospital for the reception of cases of pulmonary tuberculosis 47 cases had been admitted. 14 of the patients had died after a residence of from two days to 11 weeks. The average cost was 11½*d.* per day per patient.

The Presentation to Sir Henry D. Littlejohn.

As has already been mentioned in The Lancet, the presentation to Sir Henry D. Littlejohn is to take the form of his portrait by a leading artist. Subscribers to the testimonial would facilitate arrangements if they would send their contributions to Mr. R. N. Ramsay, Bank of Scotland, Forrest-road, Edinburgh, who is acting as treasurer.

Graduation Ceremony at the University of Glasgow.

On July 17th in the Bute Hall the summer graduation ceremony took place at the University of Glasgow. As is usually the case at this midsummer function, all the graduates were candidates for medical degrees. The degree of M.D. was conferred on seven Bachelors of Medicine, "with commendation" in one case. One student received the degree of M.B., C.M., having started his course under the old regulations, and 63 graduated M.B., Ch.B., of whom two obtained their degrees "with honours." The proportion of ladies among the graduates was much as usual, one lady appearing among those who graduated as Doctors of Medicine and five among those who graduated as Bachelors. At the close of the ceremony Professor John G. McKendrick, who is retiring from the chair of physiology, addressed the graduates. He first touched upon the great development which had taken place within recent years in universities and more especially in connexion with their own University. In dealing with the progress that had been made in medicine and surgery he said that it seemed to him that we were even now on the road to great discoveries that might, as regards some details of practice, revolutionise the medical art. It was becoming more and more apparent that physiology, pathology, and pharmacology were closely connected and on knowledge derived from these practical medicine was based. He therefore urged those who had just graduated to preserve their knowledge of these three sciences, to link them together, and they would find that each would help and illuminate the other.

Arbroath Infirmary.

At the annual meeting of the directors of, and subscribers to, the Arbroath Infirmary attention was drawn to the fact that a person suffering from pulmonary tuberculosis had recently been admitted to the convalescent home. The meeting accordingly resolved that in the case of granting certificates for admission to the home all medical practitioners should make a thorough examination to satisfy themselves in a given case that the patient was not suffering from pulmonary tuberculosis. As regards the finances of the hospital, although the balance is on the wrong side the deficit is very small. The total revenue for the year was £1178 4*s.* 11*d.* and the expenditure, including expenses connected with the convalescent home, amounted to £1194 10*s.*

July 22nd.

IRELAND.

(From our own Correspondents.)

Efforts to Check Tuberculosis in Dublin.

At a meeting of the rural district council of the South Dublin union held on July 18th Mr. D. Edgar Flinn, medical inspector of the Local Government Board, suggested that the council should join with the corporation of Dublin and the various public bodies in the county in establishing a sanatorium for the whole of the city and county. The death-rate in Dublin from consumption, he stated, was over 3 per 1000 of the population, while in Belgium and other countries where sanatoriums had been established for grappling with the disease in its early stages the death-rate had been reduced to 1 per 1000. The following motion was adopted by the council:—

> That we, the South Dublin rural district council, hereby call on the corporation and the various rural and urban districts of county Dublin to appoint representatives to form a deputation to wait on the Chief Secretary with a view to obtaining a Government grant towards the cost of a sanatorium for consumptives.

Post-Graduate Study in Dublin.

Arrangements have been made by the ten general hospitals in Dublin as well as the various hospitals devoted to special subjects, with the sanction of the President and Council of the Royal College of Surgeons in Ireland, for the holding of two courses of post-graduate study annually during the months of June and September. Each course will last for three weeks and will render the whole of the clinical material in the city available for post-graduate instruction. The various subjects are classified under the headings of medicine; surgery; diseases of children; diseases of the skin, of the eye, and of the throat, nose, and ear; gynæcology; therapeutic applications of the x rays and of light; pathology and bacteriology; lunacy; operations on the dead body; anatomy; and sanitary science. The next course will extend from Sept. 24th to Oct. 13th. A fee of 5 guineas will be charged for each course and will entitle the holder to participate in every section of the course. The instruction given will be as practical and as helpful to the varying needs of the practitioner as possible. Further information can be obtained from, and applications are to be addressed to, Professor A. Fraser at the Royal College of Surgeons, Dublin.

Tuberculosis in Cattle.

At a meeting of the committee appointed to inquire into the working of the Department of Agriculture and Technical Instruction held in Belfast on July 17th Mr. R. T. Huston, a veterinary surgeon, who is secretary of the county Armagh Committee of Agriculture and who has had, perhaps, unique experience in reference to the prevalence of tuberculosis in cattle, said that during the past eight years he had tested hundreds of cattle. Since Jan. 1st, 1905, up to the date of the meeting he had had submitted 213 animals to the tuberculin test and 164 failed to withstand the ordeal, while four were doubtful. In other words, one-quarter of the cattle in Ireland were tuberculous. He had no doubt about that and he had no doubt about the test. All diseases should be scheduled. He believed that at the present time children in Ireland were being fed largely on milk swarming with the bacilli of tuberculosis, and in his opinion it was no wonder that the death-rate was high. Mr. Huston's figures showing that one-fourth of the cattle in Ireland are tuberculous, as given before this committee, are much higher than the findings of Geddes, who in 1901–02 was sent by the American Government to examine by means of tuberculin some of the chief breeds of British dairy cattle and who reported in the Nineteenth Annual Report of the Bureau of Animal Industry, 1902 (p. 551), that of 1551 animals tested of all breeds 230, or 14·77 per cent., were rejected. The highest rejections were among the Jersey strain (54·76 per cent.), then came the Aberdeen Angus (28·73 per cent.), then the Ayrshire (24·24 per cent.), then the shorthorn (23·25 per cent.), while in the Dexter-Kerry, Guernsey (on Island), and the Sussex there were no rejections at all.

Presentation to Mr. C. K. Darnell of Bangor, County Down.

At a meeting held in the Medical Institute, Belfast, on July 17th, Mr. C. K. Darnell of Bangor was presented with an address, a piece of silver plate, and a cheque for 300 guineas from a large number of his medical brethren. Dr. J. W. Browne, who presided, having referred to the trying time through which Mr. Darnell had passed[1] and to the universal sympathy felt for him by his medical brethren, called upon Dr. W. Calwell (President of the Ulster Medical Society) who conveyed to Mr. Darnell the deep and warm sympathy, not only of the members of his society, but also of numerous medical men throughout the United Kingdom, who had joined in that presentation. He claimed for Mr. Darnell that he had "exercised a reasonable degree of care and skill"; also honesty of purpose and uprightness of conduct, which seemed to his professional brethren to entitle him to a verdict. It was only the absolutely prohibitive expense that prevented the case from being carried to the House of Lords. Dr. Cecil E. Shaw (secretary to the Ulster branch of the British Medical Association) read the address, to which Mr. Darnell having replied, the chairman made the presentation. A vote of thanks to the chairman, moved by Dr. John Campbell, terminated the proceedings. Letters of apology were read from the following subscribers to the presentation who were unable to be present: Sir William Whitla, Professor J. W. Byers, Mr. J. G. Jefferson (Lisburn), Dr. J. M. Killen (Larne), Mr. J. Rowan (Gargary), Mr. H. Buchanan Murray, Dr. Cathcart, Dr. J. S. Morrow, Mr. T. C. Nelson, and Mr. H. T. A. Warnock (Donegal).

Bangor Nursing Society.

At the annual meeting of the Bangor Nursing Society held on July 19th, the Dowager Marchioness of Dufferin presiding, Professor Byers gave an address on Infantile Mortality and Consumption, pointing out the aid which nursing societies might give in the solution of such pressing health problems. At the conclusion of the address Lady Dufferin expressed her appreciation of Professor Byers's address and her thanks to him for coming to Bangor to help their nursing association.

Visitation of the Royal University of Ireland.

Sir William Anson, Bart., M.P., and the Right Hon. Sir A. M. Porter, Bart., Master of the Rolls, held in Dublin, by command of the King, a special visitation of the Royal University of Ireland on July 20th for the purpose of inquiring into the relations between the University and the Queen's Colleges, and to solve the doubt which had arisen as to the meaning to be applied to certain words in the Act of Parliament as to the holding of prizes, scholarships, exhibitions, or Fellowships, or other emoluments by students of the University. The object of the visitation was to determine a legal point raised in the University which affected a number of the students in the three Queen's Colleges of Belfast, Cork, and Galway. It depended on the proper construction of the University Education (Ireland) Act (1879), Section 9, Subsection 4, which provides that "no student holding any exhibition, scholarship, fellowship, or other similar prize in any other university, or in any college attached to a university, or in any college endowed with public money, shall hold any of the said exhibitions, scholarships, fellowships, or other prizes in the university, to be created by the said charter, without taking the value of such previous exhibition, scholarship, fellowship, or other similar prize into account." By some it was argued that under this section a student who obtained a scholarship of, say, £20 value, at any of the Queen's Colleges and within the 12 months gained an exhibition of £40 in the Royal University, will only be entitled to receive the difference between the two amounts from the Royal University as "the value of the previous scholarship must be taken into account." On the other hand, it was argued that having once received the emoluments connected with the Queen's College scholarship the student had ceased to hold it, and did not come under the operation of the statute. If the first view had been established the holders of the many valuable scholarships in connexion with the Queen's Colleges of Belfast, Cork, and Galway would have been disentitled during the year after winning such to obtain money prizes in the Royal University without deduction, or might even receive nothing in some cases. It also meant, what was admittedly unfair, that scholarships provided by private individuals in the Queen's Colleges—who wished to encourage education—should be treated as if they were scholarships founded by public money. It was contended that it was unfair that the amount of one of these scholarships awarded to a student should be appropriated by the Royal University in the event of that student passing an examination and gaining a scholarship in the Royal University. It was, on the one hand, contended on behalf of University College, Dublin, which it was said had no public endowment, that the proper construction of Subsection 4 was one that would prevent concurrent endowments. On the other hand, it was shown that University College had 15 professors, each receiving £400 a year salary and £6000 for its arts course from the Government, whereas the arts endowment to each of the Queen's Colleges was £2633 a year and all the time University College was entirely free from all the exemptions proposed to be put in force in the case of the Queen's Colleges, while in reality it was a Government endowed College. The visitors decided (and against their decision there is no appeal) that a Queen's College student was not disqualified from holding an exhibition in the Royal University because he holds a Queen's College prize. The matter has from time to time occasioned discussions in the Senate and has aroused much unpleasant feeling among the representatives of the institutions concerned; it is therefore hoped that after this authoritative and final decision the matter will be allowed to drop.

July 24th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Malaria and Yellow Fever in Senegal.

ON July 10th M. Kermorgan read a paper before the Academy of Medicine in which he related the good results obtained by the Dakar and St. Louis Railway Company in its efforts to protect its servants against malaria and yellow fever. The improvement in the morbidity conditions was remarkable. At St Louis for the year 1902–03, before the protection of buildings by metallic gauze shutters, ten railway servants spent 139 days in hospital and were also off work for 44 days. In the year 1904–05, after the instalment of such shutters, the number of days in hospital fell to 13, while the men who were off work without going to hospital numbered only two who were off work for 13 days between them. Similar figures were reported from other stations.

Serious Insanitary Conditions in Madagascar.

At the same meeting of the same society Professor Blanchard gave a most serious account of the widespread and fatal prevalence of malaria in Madagascar. Tananarivo is considered the most healthy place in the island on account of its elevated situation. In 1900 the number of deaths from malaria was 48, in 1903 it was 137, in 1904 the number was 277, in 1905 it had risen to 688, and for the first four months alone of 1906 the deaths had mounted to 980. The population of the town is only 40,000. Professor Blanchard had studied the causes of the outbreak with great care and he had arrived at the conclusion that the primary cause lay in the works for the construction of a road and a railway from Tananarivo to the coast. These works have been the cause of bringing down the Hovas from the healthy plateaux which they formerly inhabited, and where they have up to now been free from malaria, to the low-lying coast lands Here there are two important species of mosquito—pyretophorus costalis and myzomyia funestis—which are carriers of the malaria parasite. As the railway and road are pushed further into the interior the mosquitoes travel with the gangs of navvies and as a consequence the fever also. A similar phenomenon has been observed in Mexico where yellow fever, which was formerly confined to Vera Cruz, crept along stage by stage to the city of Mexico when the railway which unites the two towns was laid down. In the case of Madagascar it is to be hoped that measures of destruction will be taken against the mosquitoes and also that the use of quinine will be insisted upon, for these two methods are the best for combating the malaria scourge.

A New Chair in the University of Paris.

On the motion of M. Roussel the Municipal Council of Paris has just decided to recommend the creation in the Faculty of Medicine of a chair of oto-rhino-laryngology.

A Case of Bubonic Plague.

On July 3rd a sailor at Havre was suddenly attacked by acute colic and nausea and being unable to work went home. In the evening of the same day, as he had become worse, a medical man was sent for who prescribed a certain course of treatment. Next day a hospital physician was called in and saw the patient twice. At his second visit he was able definitely to ascertain the presence of enlarged glands in the patient's groin and that also he showed other symptoms of plague. Three other medical men who were called in consultation confirmed the diagnosis but the patient died. Fluid was taken from the bubo which on being examined also confirmed the opinion of the medical men. Strict hygienic measures were promptly taken by the Mayor of Havre. The rooms occupied by the deceased were turned out, disinfected, and washed down with a solution of perchloride of mercury and all the belongings of the patient were burned.

Radium in Gynæcology.

On July 2nd M. Oudin and M. Verchere communicated to the Academy of Sciences the results of some experiments upon the above subject. A glass tube containing two centigrammes of pure radium bromide was inclosed in a uterine sound made of aluminium. This was passed into the cavity of the uterus and was left there for from ten to 15 minutes without any harm resulting. In two patients suffering from uterine fibroids accompanied by severe hæmorrhages the bleeding, which before the treatment had been almost continuous for many months, was entirely controlled. This effect was only to be expected in view of the well-known vaso-obliterative action of radium. Further, the microbicidal action of the radium brought about rapid and complete cure in various cases of long-standing catarrhal metritis and greatly improved chronic cases of gonorrhœal urethritis.

A New Dispensary for the Tuberculous.

A new dispensary has just been called into being on the initiative of Dr. Héricourt, medical inspector of posts and telegraphs. The object of this dispensary is to facilitate compulsory hospital treatment for tuberculous employees in this department who are only too many in number.

Chloroform Hallucinations.

A singular action for divorce has just been settled by the Tribunal of the Seine. The wife of a medical man wished to divorce her husband. She said that one day her husband went to a friend's house to operate upon the friend's nurse. When the girl awoke from the anæsthetic she said that she had seen the medical man embracing her mistress. In defence the medical man called Dr. Brouardel and Dr. Debove who both said that patients under an anæsthetic were very wont to develop hallucinations which endured after they woke up. The court agreed with this evidence and threw out the wife's pleadings on these grounds. Other indisputable evidence was, however, brought and the wife of the medical man was granted her divorce.

The Transmission of Infectious Diseases by Domestic Animals.

M. Remlinger and M. Osman Nouri, at a meeting of the Hospitals Medical Society held on June 20th, gave an account of the following case of infection. The case occurred in a family in which hygienic precautions were duly observed. The family returned to town from their country seat because scarlet fever had broken out in the neighbourhood. Some days later one of the daughters, aged 16 years, showed all the symptoms of a mild attack of scarlet fever. She was isolated and the disease ran its usual course. On the twentieth day of the illness a younger sister returned home and the strictest precautions were taken to prevent her catching the infection from her sister. 12 days after the return of the younger sister she sickened with scarlet fever. The attack was mild and the patient recovered without any complications. Every care had been taken to prevent any servant who attended on the elder sister from having anything to do with the younger one and nothing that the elder used was also used by the younger. The infection in the case of this latter patient was, however, traced to the cat which had been in contact with both patients.

July 24th.

ITALY.

(FROM OUR OWN CORRESPONDENT.)

Italian Coöperation at the Recent International Meeting of the Red Cross at Geneva.

THE Geneva Convention for the relief and care of the sick and wounded in war has always had special interest for Italians who even go so far as to claim priority in the conception of the philanthropic movement, though conceding, of course, that the Swiss were the first to "put it on wheels." Italy was therefore exceptionally well represented at the recent Conference of the coöperating parties to the Convention—a Conference held at Geneva in the historic "Alabama" Hall of the Hôtel de Ville and marking, on its dissolution a few days ago, a distinct advance on the programme agreed to by its predecessors. The Federal Council had compiled, on the basis of deliberations ratified at the Hague Congress, a series of questions to be examined by the Conference and these, 14 in number, dealt with the following subjects: (1) the wounded, the sick, and the dead; (2) the medico-chirurgical *personnel;* (3) the medico-chirurgical *matériel;* and (4) signals, abuses of the same, and general questions. On the motion of his Excellency M. Edouard Odier, Swiss Minister at the Court of Russia, elected by acclamation President of the Conference, these four groups of subjects were submitted to as many committees formed from the delegates of the nationalities represented, whose findings finally came up for ratification in plenary assembly. To begin with, the protection accorded by the Convention of 1864 to the sick or wounded in war without distinction of nationality was extended to all persons officially attached to the Army Medical Service; in other words, to all officially charged with picking up, transporting, and tending the sick or wounded, to the working staff of the several medico chirurgical bodies, and to the ministers of religion. To this provision, formally re-stated in terms more juridically exact than previously, exception was taken on the ground that the Geneva Convention could guarantee no real protection to the medico-chirurgical *personnel* as above defined, and a motion was introduced to exclude the said *personnel* from the Convention. An animated discussion followed, in which a powerful vindication of the provision was given by General Randone, Inspector-General in the Italian Army Medical Department, and, as a consequence, the motion was rejected well-nigh unanimously. On the important question of voluntary aid (*soccorso volontario*) the Conference came to a conclusion more precisely defined than heretofore and its terms ran thus: "We assimilate to the official *personnel*, to be under the protection of the Convention, the *personnel* of the societies of voluntary aid duly recognised and authorised by their Governments, the said *personnel* to be employed in the medico-chirurgical formations of the armies, under the reservation that it will remain subject to the military laws and regulations." Minor questions cropped up in the discussion of this provision but without affecting it substantially, one point, however, standing out with special clearness—viz., that as a direct consequence of the protection accorded by the Convention to all the *personnel* officially attached to the sick or wounded in war, the said *personnel*, if it fall into the power of the enemy, will not be treated as "prisoners of war." As to the moveable *matériel* of the Red Cross service, it was unanimously agreed that it ought to be treated differently from the permanent military hospitals belonging to the State and planted almost invariably on national territory. These last must remain subject to the laws of war, while their medical purpose will always be respected; the moveable *matériel* of the Red Cross, on the contrary, will be in all circumstances inviolable—a conclusion which, again, the experience and the arguments of General Randone powerfully reinforced. Thereafter the Marchese Maurigi, another of the Italian delegates, secured the reaffirmation of the principle already recognised at the Hague Congress that benevolent institutions maintained by such organisations as the "Opere Pie" of Italy shall be considered as private property and not come under military law. The treatment of the wounded was another question more stringently dealt with than at previous conferences, the conclusions discussed and formulated all tending to minimise the risks to the victims referred to while securing greater facilities for the emissaries of the Red Cross. As to the search for the wounded and their protection, equally with the dead, against plunder and ill-usage, the conclusion formulated sets forth that after every combat the master of the field of battle will take the necessary measures *ad hoc*. The said master will equally take upon himself the inhumation or incineration of the dead, but only after an attentive examination of their bodies. Besides, it will be his duty wherever possible to send to the authorities of their native country or army the insignia or regimental marks of identification found on the bodies and a specific statement of the condition of the sick and wounded. Finally, the regulations affecting transport, particularly "convoys of evacuation," were once more reviewed and brought into closer correspondence with respect for the sick and wounded on the one hand, and with the military law on the other, the transport service (wagons, trucks, &c.) not being available for other than the special purposes of the Red Cross. And so the conference rose, having fulfilled its beneficent programme with a more circumspect eye to the interests of the immediate sufferers from war than was possible to its predecessors to whom the experience of later military developments was necessarily denied.

"*Drowned at Sea.*"

One of the most brilliant graduates of the Venetian school, Dr. Antonio Dal Fabbro, who had chosen the Congo as his professional field, went down (so I have just learned from Verona) with the steamer that was conveying him to Kassai. Of his 80 fellow passengers only three saved themselves by swimming, while Dr. Antonio, though a strong swimmer, could not avail himself of his powers, having been in his cabin at the moment when the vessel struck. He was but 29 years of age and had taken the degree of Doctor of Medicine in 1899 with special honours for his thesis on "Progressive Paralysis." He subsequently settled at Banana in the Congo and remained in practice for three years. In 1904 his father, Professor Francesco Dal Fabbro, himself a distinguished consultant of the Venetian School, fell ill and Dr. Antonio returned to his native Verona to assist him. In the autumn of 1905 he went back to the Congo, where, as already stated, he met his death off Kassai. His friends and colleagues have now raised a sum sufficient to endow a bed associated with his name in the wards of the "Colonie Alpine" hospital—a worthy tribute to a physician whose post graduate studies culminated in a "diploma di perfezionamento" in gynæcology and obstetrics.

The Health of the Pope.

Concerning Leo XIII. it used to be asked, "If sensational paragraphs about his health should cease to be a *locus communis* in journalism, what would the continental quidnunc do for a livelihood?" His successor, Pius X., has barely been three years in the Holy See and already he seems qualifying for a similar rôle. The other day he gave audience to a party of the faithful, when it was remarked that he had a finger bandaged. That very evening it was announced in various of the European capitals that His Holiness had had another attack of the gout—not in the knee this time. What are the facts? Some 24 hours previously he had been at his escritoire, and in the act of removing from a penholder a rather stubborn nib the latter had run into his finger just under the nail. Having washed the puncture and dressed it himself without disturbing anyone His Holiness next morning had a visit from Dr. Lapponi, who undid the dressing, re-washed the wound, and then re-bandaged it *secundum artem*. So much for the "fresh attack of gout—this time in the hand!"

July 22nd.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Rupture of an Aneurysm of the Aorta into the Vena Cava.

AT a recent meeting of the Medical Society Dr. Herz showed a man giving a history to the effect that he suddenly felt something give way in his breast and that the skin of his head and face became cyanotic shortly afterwards. When he was brought into hospital there was extensive œdema of the face, the upper part of the thorax, and the upper limbs, with dark-blue discolouration. The external jugular vein, although not distended, was well filled and had a rhythmical systolic pulsation; on the right side of the sternum there was a prominence in which pulsation appeared now and then. In this region there was a triangular space where a loud high-pitched whistling sound was audible. Under digitalis the œdematous swellings were reduced in size. The diagnosis of rupture of an aortic aneurysm into the vena cava was proved to be correct by the necropsy which took place just a day before the next meeting of the society and Dr. Herz was able to show the aneurysm at the meeting. The cyanosis and the whistling noise, together with the symptoms of pressure and pulsating veins, have been present in all cases of a similar type reported hitherto.

Cancer Research.

In order to obtain as full information as possible on the mode of propagation of cancer, its distribution amongst the population of certain districts, its occurrence in the successive occupants of certain houses, the possibility of infection, and the alleged increase in the number and malignancy of the cases a collective investigation by all medical practitioners has been arranged, and the instructions which are to be sent out to all members of the profession throughout the Austrian empire have been got ready. An attempt will be made to show separately the different groups of organs attacked by the disease by appealing to the general practitioners as well as to the specialists, but a novel feature will be an endeavour to prevent a multiple notification of the same case by the family practitioner, the specialist, and possibly the surgeons and other medical men who might be consulted before an operation takes place. Medical men will be requested to ask the patients whether they have been already examined, and if so by whom, and to supply these data, together with the name of the patient, to the central committee. This will, of course, greatly increase the labour of tabulating the returns, as the names of both the previous medical attendants and the patients will have to be looked up several times in the register but the gain in the accuracy of the figures which will be obtained in this way will be well worth the extra expenditure of time and trouble. Both medical men and veterinary surgeons are also invited to give attention to cases of malignant growth amongst domestic animals and cattle; valuable information on this subject might be collected but the difficulty of making post-mortem examinations on animals, and especially on animals of considerable age, is almost insuperable, whilst the results derived from slaughter-houses are not worth much because the animals killed there are comparatively young.

A Case of Wrongly Diagnosed Abdominal Pregnancy.

Pregnancy outside the genital canal is a rarity well worth recording. Therefore Dr. Lindenthal had a very attentive audience when he gave the details of such a case before the Gynæcological Society and was able to show not only the fœtus but also the anatomical preparation and the living patient who supplied the interesting abnormality. It appeared that the woman in question had been advised by her medical attendant to undergo an operation and when she came to the hospital the diagnosis of an intra-uterine pregnancy and an intra-ligamentary cyst of the left ovary was made. The examination showed a large uterus, displaced by a large cystic swelling towards the right side, but on opening the abdomen the uterus was found not pregnant although it contained a membrana decidua, one-third of an inch thick, and had hypertrophied walls. The real cause of the cyst was a living fœtus, ten inches long, and the sac in which it lay had opened up both layers of the ligamentum latum, the mesosalpinx, and the meso-rectum. With the naked eye it could be seen that the ovary and the tube had nothing to do with the sac and microscopic examination confirmed this evidence. The tube ran across the upper surface of the ligament, both its openings were free, and the lumen was pervious. The ovary was situated on the lower end of the sac, compressed into the shape of a flat plate. As regards the mode of development of abdominal pregnancy, three explanations are possible—namely: (1) re-implantation of the ovum after rupture of the tube; (2) a direct implantation of the ovum under the serosa of the parietal peritoneum; or (3) arrest of the ovum on the fimbriæ, with subsequent growth between the two layers of the peritoneal folds. Only the latter two ways are probable, according to the experience of authorities on the subject.

A Proposal to Tax Medical Prescriptions.

Endeavours are being made to increase the funds at the disposal of the medical councils and the medical provident institutions, and among the schemes which have been suggested for the purpose there is one which has deservedly found great approval. Starting from the consideration that the public derives the largest benefit from the hard work done by the medical profession the idea that the public should contribute to the funds necessary for the internal organisation and the benevolent agencies of the profession is very attractive. It has therefore been proposed that money should be raised for this purpose by affixing to each prescription every time it is made up a stamp having the value of one kreutzer (less than a farthing). The stamps would be obtained by the pharmaceutical chemists from the various medical councils and boards and it would be unlawful to dispense any prescription without such a stamp. Taking the number of practitioners in Austria at 10,000 (in reality there are many more) and estimating that each practitioner writes daily only one prescription this would bring in at least £3000 a year. The money thus realised would be laid out on old age pensions, grants to orphans and widows, and the maintenance of certain medical institutions.

A Unique Case of Embolism of Air combined with Embolism of Septic Material.

At a recent meeting of the Medical Society Dr. Richter showed some pathological specimens obtained from a woman 22 years of age, a primipara, who after a miscarriage at the eighth month and slight septic fever suddenly became collapsed whilst partaking of food and died in a few seconds. At the post-mortem examination it was found that the right ventricle of the heart was greatly distended with gas and when it was opened under water a large number of bubbles of gas of the size of a walnut came out of it. The pulmonary artery was filled with hard greyish-red clots measuring as much as three inches by half an inch. The source of both emboli was found in the uterus, from the cavity of which a probe could be passed without encountering any resistance whatever through the site of the placenta into a vein, its path being an aperture about a quarter of an inch in diameter which led directly to the plexus uterinus and the vena cava. The last-named vessel, as well as some other veins, were filled with atmospheric air, whilst the majority were hard and contained thrombi and other septic material. The uterus was very soft, its involution was making little progress, and the cervix admitted two fingers. No doubt the exertion of sitting up had loosened the thrombosed masses in the uterine veins and had produced embolism of the pulmonary artery. When the woman sank backwards the suction produced by the uterus opening or sinking into the pelvis allowed air to enter the uterus from which it passed into the veins and ultimately into the right ventricle. In making a necropsy care must be taken that gases produced by decomposition or air entering the subclavian vein during the act of removing the sternum be not confounded with air entering the vessels or the heart during life either as a result of surgical operations or injuries or through the uterus.

CONSTANTINOPLE.

(FROM OUR OWN CORRESPONDENT.)

Sea Baths.

IN suitable circumstances there can be nothing more refreshing and exhilarating than a bath on the magnificent shores of the Bosphorus, where the mightily heaving current is ever deep and pure and cool. Unfortunately, bath pavilions are indiscriminately erected here without taking the necessary precautions as to the hygienic conditions of the site; indeed, it often happens that a sea bath is established in the proximity of drains. I learn that the Ottoman Government has decided to remedy this unsatisfactory state of affairs and that it has given instructions to the Imperial Medical School to take all the necessary steps in order to prevent further construction of sea-bath pavilions in unsuitable or unhealthy places. The Imperial School, in conjunction with the prefecture of the city, will appoint a sanitary commission the duty of which it will be to select the proper sites on the Bosphorus, on the Sea of Marmora, and on the Golden Horn, where bath establishments should be erected. The construction of the public pavilions will receive more attention, so that they may comply, not only with the exigencies of æsthetics, but also with those of hygiene, and proper inspection of bathing towels and garments will be exacted.

The Maternity Hospital.

The Sultan has authorised the opening of a subscription for the funds necessary to construct a maternity hospital in Constantinople and has started the collection with a liberal donation.

Another Bacteriological Institute.

It has been decided to construct a bacteriological institute in connexion with the Veterinary School. The foundation-stone has already been laid last week. The Government will furnish this establishment with the necessary material and instruments for the production of diff-rent antitoxic sera. The latter will be produced in sufficiently large quantities to be able to supply the whole extent of the Ottoman Empire and to combat the various epizootics which from time to time attack the provinces, sometimes with great violence. The Minister of Agriculture, Selim Pasha Melhamé, has taken a laudable interest in the new establishment.

The Industry of Rose Essence.

It has been discovered that the distillers who are occupying themselves with the industry of rose-essence production in the vilayet of Hudavendighiar have been in the habit, up to now, of mixing with the pure essence of roses all sorts of extraneous matter. In consequence of this the industry has fallen somewhat into disrepute. The commercial authorities have therefore taken the most energetic measures to prevent further falsifications by the provincial distillers. A special commission has lately visited the distilleries of the above vilayet and has taken the necessary steps against fraudulent practices.

July 13th.

NOTES FROM INDIA.

(FROM OUR SPECIAL CORRESPONDENT.)

The Indian Nursing Association.

THERE has been felt for many years a great want of skilled European nurses for Europeans in Northern India and an attempt made a few years ago to establish an association unfortunately fell through. The scheme has recently been taken up again and is now receiving more official support. It is proposed to provide sufficient English trained nurses in the various provinces of Northern India and Burma for all classes of Europeans. Other outlying provinces where no regular nursing organisation now exists will be included. The proposed association will be controlled by a central committee containing representatives from each province. There will also be provincial committees for local control. The fees to be charged for the services of these nurses will be on a sliding scale as it is desired to place skilled nurses at the disposal of both rich and poor at a moderate rate and commensurate with their incomes. Thirty-eight nurses with a chief lady superintendent and two lady superintendents will at first be employed. The value of this scheme can only be realised by those who know India and who have been able to recognise that many valuable lives have been lost through want of proper nursing, more especially in outlying districts. The want of trained nurses has been the cause of much suffering.

The Strike of Students in Lahore.

The remainder of the medical students on strike in Lahore have submitted unconditionally and have petitioned to be allowed to resume their studies.

Plague in the Burma High Court.

The Burma Chief Court has had to be closed in order thoroughly to be disinfected and cleaned. On June 23rd several dead rats were discovered in the record rooms behind the records and under the judges' platforms and examination has revealed the fact that the rats found have plague bacilli. The interruption of the judicial work of the courts is no small matter and the sanction of the Lieutenant-Governor had to be obtained by wire. Plague still lingers in Rangoon; in fact, the deaths are increasing in number, and a recrudescence of last year's outbreak would not be surprising.

The Plague Epidemic.

The epidemic throughout India has sunk to insignificant proportions, only 1904 deaths with 2224 seizures being reported for the week ending June 6th, more than half of which occurred in the Punjab. The mildness of the epidemic this year throughout the whole of India is remarkable and it certainly cannot be attributed in any way to the plague measures adopted. It will be remembered that in the Bombay Presidency last year a very marked amelioration occurred, only 71,000 deaths being recorded, as against nearly 300,000 in 1903. A curious feature in the figures is that the decline was greatest in those districts which had suffered most severely in past years.

The Adulteration of Opium.

It may interest pharmacologists to know with what materials opium is adulterated in India. An important case tried at Hyderabad brought out the fact that "sangzira" was mixed with opium in large quantities, that the mixed opium was soaked in linseed oil, and that finally "amul" was added. It was also admitted that "bhang" was frequently put in and gum was utilized to unite the ingredients and make them hard. Several witnesses said that strychnine and black sand were used in addition to some of the other adulterants.

Sickness in the Andaman Islands.

The administration report concerning the penal settlement of the Andaman Islands always contains points of medical interest. These islands are not particularly healthy as dysentery, pulmonary tuberculosis, and malarial fevers claim a heavy toll. The percentage of deaths from pulmonary tuberculosis is enormous (22·27 on the total population of the islands). There were 100 deaths amongst the 14,118 prisoners. Strict segregation of phthisical cases has been recently enforced but the general prison ccommodation is deficient. In the temporary thatched arracks which had to be erected only 36 square feet per ıan was allowed and the phthisical wards of the hospitals rere overcrowded. New barracks, however, have since been onstructed. Malaria caused 14,455 admissions to hospital. he anopheles mosquito flourishes in the islands but gangs ave been actively employed and a great reduction of these nsects has been effected. Both Megarhinus and Aedes pecies are found in addition.

June 29th.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Hospital Affairs.

THE Salvation Army has established a new hospital in Melbourne which was formally opened by his Excellency the Governor of Victoria on May 29th. The institution is designed to take an intermediate position between public hospitals and private hospitals and nursing homes. It will take in all classes from the rich to the extremely poor, but mostly those who would simply pay the actual expenses. Apart from the medical officers all the work will be done by Salvation Army officials. A large private residence has been adapted to hospital requirements and accommodation provided for 46 patients, including maternity cases. Before the ıospital was opened some difficulty arose as to its registraion. According to law an application to register a private ıospital by other than medical men must be made to the local municipal council, which in this instance refused to register. Then an application was received from Mr. A. Honman, who is one of the medical officers of the new establishment, to be registered by the Board of Health in respect of this hospital. He was called before the Board and asked whether the institution was not conducted by the Salvation Army. He rather evaded the question, replying that he was the *boná-fide* applicant for registration. Now the Salvation Army has applied to the Board for registration, which the board has refused, as "the Board could not be a party to any such irregular procedure as that suggested, as that would imply that the Board viewed with complacency the using of Dr. Honman as what might not altogether unfairly be characterised as a stalking horse in regard to this matter."—At a special meeting of the directors of the Royal Prince Alfred Hospital, Sydney, the report of the secretary upon the result of his investigations into hospital administration in Europe and America was considered. The following recommendations of the secretary were agreed to:—

> 1. The establishment within the hospital area of a Royal Prince Alfred Hospital Sunday Fund. 2. The establishment of a Ladies' Auxiliary Society to make and provide linen, &c. 3. The establishment of a hospital alliance of young people to undertake particular special duties. 4. The establishment of a collecting organisation for outside areas. 5. Application to be made to the Admiralty, through his Excellency the Governor, for a share of naval patients. 6. Reorganisation of the system of receiving casualty patients and making the casualty department an adjunct to the out patients department. 7. Registration of the names and diseases of all out-patients on the card system. 8. Payment by out-patients, except in extreme cases of destitution, as follows:—(a) 3d. for each supply of medicine; (b) 3d. for each new bottle supplied; and (c) 2d. for each surgical dressing. 9. Reorganisation of accommodation for the out-patient departments and the expenditure of £150 on the consulting rooms and equipment. 10 Adoption of the card system of registration for the following purposes: (a) registration of in patients; (b) registration of out-patients and their diseases; (c) registration of diseases and operations; (d) registration of subscribers.

The following appointments to the medical staff of the Royal Prince Alfred Hospital have been made: honorary physician, Dr. G. E Rennie; honorary surgeon, Dr. Charles MacLaurin; honorary medical officer in charge of the lock department, Dr. William J. Munro; honorary medical officer in charge of medical gymnastics department, Mr. Reuter E. Roth; honorary assistant physician, Dr. J. I. C. Cosh; honorary assistant surgeon, Dr. J. Morton; honorary assistant ophthalmic surgeon, Dr. J. C. W. Halliday; and honorary assistant gynæcological surgeon, Dr. Fourness Barrington.—At a special meeting of the subscribers to the Women's Hospital, Melbourne, certain amendments in the by-laws relating to the appointment of the honorary medical staff were passed. It is now provided that the committee instead of the subscribers should elect the honorary medical staff consisting of 12 officers. In addition to the 12 honorary medical officers appointed the committee was to have discretion to appoint as a member of the staff *ex-officio* the lecturer on obstetrics at the University of Melbourne. With the exception of this officer, whose appointment was to be for such time as the committee might think fit, the honorary medical staff was to be elected for a period of seven years. On attaining the age of 60 years any honorary medical officer was to cease to hold office in the hospital, but the alteration was not to lengthen or shorten the terms of office of any honorary medical officer appointed before the by-law came into operation. Provision was also made to insure that candidates should be properly qualified.

Use of the Title of "Dr." by a Dentist.

At an open court held by the Dental Board of New South Wales under the Dental Act Mr. Bradley was charged with "infamous conduct in a professional respect" by using a brass plate with the prefix "Dr." to his name, adding thereto his university degree, "B.D.S." The question was raised whether a dentist holding a bachelor's degree was entitled to call himself "Dr." by analogy to the similar practice in the medical profession; and, if not, whether it amounted to "infamous conduct" under the Act. The court gave the following decision:—

> That the conduct of Mr. Bradley in assuming the title of Doctor, he having only obtained the degree of Bachelor of Dental Surgery, is such as this board condemns. Such conduct, however, appears to have been based upon a supposed claim of right to establish a practice similar to that which obtains in the medical profession. In the circumstances, the board will take no action in this case. The board, however, reserves to itself full liberty of action if, in view of the opinions now expressed, the practice is persisted in by Mr. Bradley or any other registered dentist in this State.

Action against Mr. Howse: Appeal Refused.

It will be remembered that Mr. Neville R. Howse, V.C., appealed to the Full Court against the decision given in the action against him, in the case where a patient was burned by hot bottles, and the Full Court decided in his favour. Application was made for an appeal against the decision of the Full Court to the High Court but has been refused as the case involves questions of facts, not of law. Mr. Howse is thus to be congratulated on the finally successful issue of a very trying case.

Action for Burns by the Tallerman Bath.

At the Sydney district court on May 21st an action was brought against the proprietor of an establishment for providing electric baths, Tallerman treatment, &c., for burns received during treatment. The judge said on the evidence before him it was perfectly clear that the plaintiff had been burnt while under treatment. Ordinarily, it would appear from the evidence that the defendant conducted her business in the most careful way but the evidence in this case pointed to the fact of the plaintiff having been burnt on this particular day. There was no doubt the plaintiff had suffered very serious loss. He had practically been out of employment for several months and in addition had to pay 20 guineas for medical treatment, besides incurring other expenses. He gave a verdict for the plaintiff for £130.

June 10th.

FREEMASONRY.—The consecration of the "Dr. James Griffith Hall Lodge" took place on July 20th at the Masonic Hall, Swansea. There was a good attendance, amongst those present being Lord Llangattock, the Provincial Grand Master of South Wales.

MEDICAL FEES IN ST. PETERSBURG.—The municipal medical officers are extremely discontented, says the *Novoe Vremya*, with the rates of payment fixed by the town for night visits and 42 of them have petitioned the sanitary committee to raise the fees in the case of those able to pay to from 4*s.* to 6*s.*, and to from 1*s.* 6*d.* to 2*s* for those of limited means. They have added another request to this one—namely, that Dr. Gordon (who is alleged to have been unjustly dismissed by the sanitary committee) may be reinstated in his position.

MEDICINE IN TORONTO.

I.

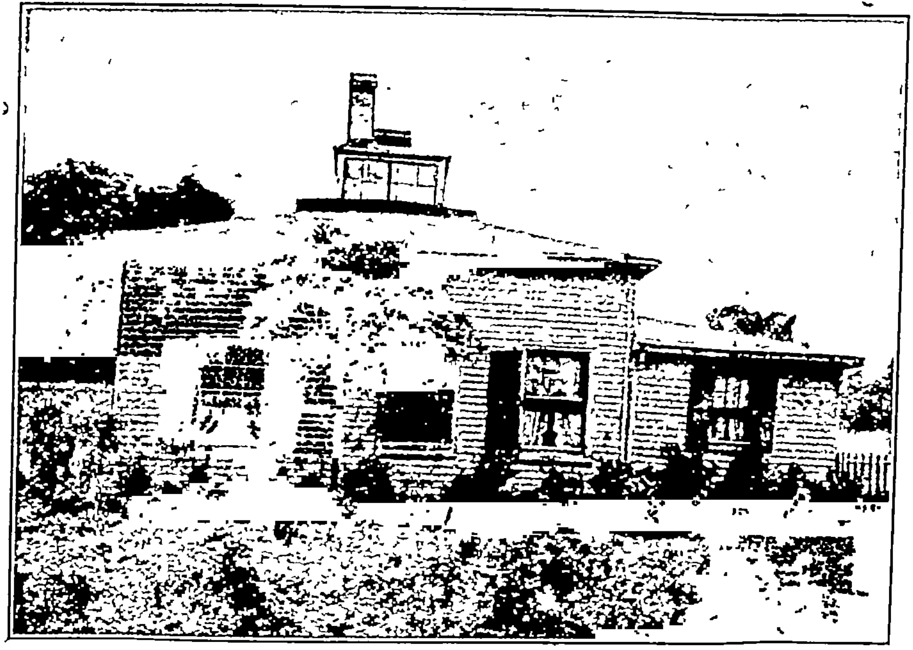
The Early History of Medicine in Ontario; A Few Notes on Some of the Pioneers.

In view of the forthcoming meeting of the British Medical Association in Toronto it will be of interest to the readers of The Lancet, whether they intend to visit the beautiful city on Lake Ontario in August or not, to learn something of the history of medicine in Ontario, as Upper Canada is now called. A perusal of this short series of articles will show that the medical schools of Ontario have gone through troublous times, as might be expected since their history runs coincident with both the development of scientific medicine and the development of Canada as a country. While Canada was working its way from a collection of backwood settlements to a highly organised Dominion, and thence to its present proud position among the most promising countries of the world, medicine almost simultaneously has evolved from empiricism, through the various stages of performance marked by individual great achievements, to its present state, one of high efficiency but especially one of boundless promise. The two evolutionary processes have progressed in Canada hand in hand and make the study of early medicine in Canada particularly interesting. The story also shows that the battles for reform in great constitutional affairs and in medical politics have ended, as they should, and as the story of our civilisation shows that they almost invariably do end, in the complete triumph of the cause of progress. At the present time the standard of medicine in Canada generally is very satisfactory, commensurate, indeed, with the place which the Dominion is certain to hold in the world's history, while medicine in Ontario forms a particularly instructive example of social development. The writer of the following chapters has not dwelt with any emphasis upon the suitability of Toronto as a meeting place of the British Medical Association, taking it for granted that the beauty of the city and its site are known by repute to all of us. Standing on the shores of its splendid inland sea, wonderfully endowed by nature with all the qualities that make a great human settlement sanitary as well as beautiful, in close connexion with the vast and stimulating western republic, and linked up by rail and water with boundless hinterlands in all stages of development and fertility, Toronto could hardly escape becoming an important capi The city has had its waves of depression following its peri of too previous exaltation, many fortunes have been lost well as made within its undefined boundaries, there h been disappointments as well as triumphs, but far-sight men have never felt in doubt as to the ultimate hi destiny of Toronto, and those who believe that the strai road to a future of grand prosperity has now been reach number among them some of the shrewdest heads in empire.

We are here, however, concerned only with the history the development of medicine in the colony.

Up to the year 1776, the time of the American Rebelli the province of Ontario was a dense wilderness. Its surv was begun in 1783 and in the following year its settleme commenced. The medical men who practised among t English people residing in Canada immediately after t rebellion were almost entirely British surgeons belonging the navy or the army, and all that has come down to us co cerning them will be found in a very interesting boo "The Medical Profession in Upper Canada," written Dr. W. Canniff, which has been freely drawn upon he With the increase of British settlers in Ontario the supp of service medical men was found to be insufficient. Some surgeons retired from the service and took up their abode in the province, while a few came out from the old country and made their home in Upper Canada.

Fig. 1.



he First Medical School in Upper Canada.

The first Act relating to medicine in Canada was passed in 1788 and shows an early appreciation of the benefits of a properly organised professional service. A copy of this Act may be seen in the Toronto Public Library and its title reads in part as follows :—

> An Act or Ordinance to prevent persons practising physic and surgery within the province of Quebec, or midwifery in the towns of Quebec and Montreal without licence.

(It must be borne in mind that Upper Canada was at that time a portion of the province of Quebec.) The Act went on to state that to obtain such a licence a person must have been examined and granted a certificate by medical men appointed for the purpose by such personages as the Governor or Commander-in-Chief of the province. Surgeons of the navy or the army or any persons who had taken a medical degree in any University were exempted from the provisions of this Act.

The next governor of Upper Canada was Peter Hunter, ated to be one of the numerous brothers of the famous ohn Hunter, in the year following whose death a second edical Act was passed which repealed the former Act. So ar as medical legislation was concerned after the repeal of he first Act matters were at a standstill up to the year 1815, vhen another Act was passed entitled "An Act to Licence ractitioners in Physic and Surgery." This Act was enacted y, and with the advice and consent of, the Legislative ouncil and Assembly of the province of Upper Canada and vas a lengthy document the regulations in which were airly strict and comprehensive. It appears, however, not o have been very practical, for in 1815 the number of ualified medical men in Upper Canada was about 0 but there were many unqualified men and a considerable number of quacks. The Act passed in 1815 was epealed in 1818 by a new Act. This Act was the strictest s yet enacted and was indeed the first effective step in he direction of placing the medical profession of Upper anada upon a proper and dignified basis. The most mportant provision of this Act was that ordering the ppointment of a medical board empowered to examine, and f considered fitting to grant licences to, those desirous of ractising medicine in Upper Canada. This board came nto force on Nov. 27th, 1818, and on Jan. 4th, 1819, the oard was convened at York, as Toronto was called at that late in its history. The records of this board are contained n two volumes now in the custody of the Registrar of the ollege of Physicians and Surgeons of Ontario and its ninute books provide very instructive and interesting reading. The board appears to have been mindful of its duties nd responsibilities so far as may be gathered from the ninutes. For example, it is recorded that a large number f would be practitioners of medicine were disqualified as nfit, though the details of the examination are not forthcoming. Probably general evidence as to training was ccepted

A minute of Oct. 8th, 1819, is especially interesting, as t contains an account of the proposals to build the first ospital in Toronto. The announcement with regard to this matter was as follows:—

> Proposals for building by contract a brick hospital in the town of York will be received at the Post Office by William Allan, Esq, where a plan, elevation, and particular description of the intended building may be seen and any information respecting it obtained

Referring to this building Dr. Canniff says that it is uncertain how soon thereafter the hospital was erected, but reference is made to the hospital in the weekly register for 1822 so that no very prolonged delay took place.

With regard to this building the late Dr. Scadding, rector Holy Trinity, Toronto, records in his interesting book 'Toronto of Old" that—

> The old hospital was a spacious, unadorned, matter of fact, twotorey structure of red brick, one hundred and seven feet long and ixty-six feet wide. It had the peculiarity of standing, with its sides recisely east and west, north and south. At a subsequent period it onsequently had the appearance of having been jerked round bodily, he streets in the neighbourhood not being laid out with the same precise regard to the cardinal points The building exhibited recessed galleries on the north and south sides and a flattish hipped roof The interior was conveniently designed

The Medical Board at its meeting in April, 1832, spoke of the hospital in terms which show that the institution was recognised at once as a centre for medical education, the following being the minute:—

> The York Hospital is now in successful operation and affords to students daily opportunities of observing diseases and their treatment, and they feel it a duty to point out to students that it is at such institutions they can best acquire, at the bedside of the patient under experienced practitioners, the practical information most especially befitting them to render professional services to their fellow creatures.

In 1832 Dr. John Rolph, a most original and interesting man to whom future reference will be made, was commissioned a member of the Medical Board and undoubtedly exercised great influence upon its deliberations. In the same year Toronto was devastated by an epidemic of cholera, with which the members of the Medical Board, in their capacity as advisers to the Board of Health, showed themselves able to cope most effectually. Many of the views expressed by them 58 years ago might have been uttered by a modern sanitarian so clearly are the benefits of hygiene and the results of its neglect laid down.

In the year 1837 the Medical Board, which had in the meantime been reconstructed, carried on a lengthy correspondence with the authorities of King's College (now the University of Toronto) and the Lieutenant Governor of the province as to the advisability of establishing a medical faculty at that seat of learning. The board strongly recommended the creation of such a faculty, but its views and those of the Lieutenant-Governor and his advisers clashing on many important points the scheme fell through. Eventually in 1839 the College of Physicians and Surgeons of Upper Canada was founded, the majority of the members of the Medical Board having been appointed Fellows. Soon after the incorporation of the College of Physicians and Surgeons its governing body made overtures to King's College to coöperate and conjointly to establish a school of medicine. The authorities of King's College, however, refused the offer. In 1840 the legal status of the College of Physicians and Surgeons was called in question, and in January, 1841, the Act establishing the school was disallowed. During its brief and somewhat chequered existence the College of Physicians and Surgeons of Upper Canada undoubtedly deserved well of the public and of the medical profession. Dr. Canniff bears the following testimony to its work:—

FIG. 2.

Dr. Christopher Widmer.

> The efforts of these comparatively early medical men to raise the character of the profession, to establish a Canadian Medical School that the young men of the province should not be obliged to go abroad for medical instruction, are worthy of all commendation. Nor may it be supposed that their work was in vain. The seed sown by them has resulted in a rich crop, reaped by the later generations of our profession in the province. No one can read the Transactions of the College of Physicians and Surgeons of Upper Canada without being impressed with the fact that the governors had lofty aims and the interest of the profession fully at heart, at the same time looking to the welfare of the public, and it must not be forgotten that their work was performed more than half a century ago.

The dissolution by legal methods of the College of Physicians and Surgeons brought the Act of Parliament under which the old Medical Board was formed again into force. It once more began its sittings and in January, 1842, presented a memorial to His Excellency the Governor General of Canada as Chancellor of the University of King's College, praying that a Faculty of Medicine might be established in that University. The Lieutenant Governor acceded to this request, while in February of the same year a resolution was passed by the council of King's College stating that for the purpose of affording the necessary facilities to students in the Faculty of Medicine it would be advantageous if the Toronto General Hospital were for the present utilised. The council proposed accordingly to devote an annual sum to the maintenance of beds for a certain number of patients in addition to those which the funds of the hospital trustees already enabled them to provide. Thus after long and repeated efforts a medical school was established in Upper Canada, in proper connexion with a university faculty and with a hospital where teaching facilities could be obtained.

The report of the newly formed medical faculty, made at the end of December, 1843, recommended among other measures that immediate arrangements should be made whereby the professors of the medical faculty should have either the exclusive medical superintendence of the hospital or a certain number of wards reserved for their sole use. It was ordered that for the present the rooms occupied as the museum and workshop should be the apartment wherein the school of medicine should be conducted and that the business of the school should commence there on Monday, Jan. 15th, 1844, and that a frame building erected on the north or west side of the western wing would be sufficient for the above purposes. This building was to be erected forthwith. This plan was carried out as recommended and the first building in connexion with the first university medical school of Upper Canada was erected in 1844. (Fig. 1.)

Among Canadian fathers of medicine and surgery, to turn to the personalities of the pioneers, the foremost place is without doubt due to Dr. Christopher Widmer. (Fig. 2.) To Dr. James Henry Richardson, himself one of the best known medical men to this and a past generation in Toronto, we are greatly indebted for personal reminiscences of Dr. Widmer and of other early Canadian medical practitioners. Dr. Widmer was a Member of the Royal College of Surgeons of England and before coming to Canada had been staff-surgeon attached to the 14th Light Dragoons. He served through almost the entire Peninsular war and came to Canada 1812–15. He commenced practice in York (Toronto) about the year 1816 and died there in 1858. As a surgeon he is reported on all hands to have possessed the highest skill, and he took the greatest possible interest in all appertaining to his profession. He was a member of the Upper Canada Medical Board from the time of its inception in 1819 and chairman from 1823, and the guiding spirit of the general hospital from its foundation. He was a public-spirited citizen as well as a really great surgeon. Dr. Richardson's first recollections of Dr. Widmer date from 1837 and he describes him as a small and wiry man, with a somewhat unhappy look but with keen eyes. In speech he was abrupt and commanding, given to the use of strong and forcible language, but withal extremely kind-hearted.

Of all the early medical practitioners in Toronto perhaps, on the whole, the most gifted and celebrated was Dr. John Rolph. He had a stormy career, for he lived in stirring times and was himself a moving spirit in the Mackenzie rebellion of 1837. Dr. Rolph in his day played many parts, for he was distinguished as a politician, as a physician, and as a member of the Bar. But it was as a teacher of medicine that he chiefly shone. In this branch of medical science he was pre-eminent. Dr. Rolph came out to Canada from Gloucestershire, in which county he was born, very early in the century. Dr. Richardson thinks he emigrated about 1812, at which time he would have been 19 years of age. He probably, however, did not emigrate to Canada until a few years later. He had been educated at Guy's Hospital Medical School and was a pupil of Sir Astley Cooper. He became a Member of the Royal College of Surgeons of England and is supposed to have returned to England to prosecute his law studies after he had originally reached Canada. At any rate, he became a member of the Inner Temple and practised in Canada both in law and medicine in the year 1831, when he also took an active part in politics. After the failure of the 1837 rebellion Dr. Rolph, who had joined William Lyon Mackenzie in his plot against the existing Government, fled to Russia, but after a time returned to the United States and practised in Rochester up to 1843, when the ban was removed by Act of Parliament and those who had taken part in the rebellion were allowed to go back. Soon after his return he founded a school of medicine which in 1853 was incorporated under the title of the "Toronto School of Medicine," of which more later. Dr. Richardson describes Dr. Rolph as dignified in appearance, quiet and precise in speech, with absolute self-control, courtly in manner, a profound reasoner, and a charming and persuasive orator. He was certainly one of the most influential members of the Reform party in Canada and that party has had its influence upon present day Canadian prosperity. He was also well versed in all branches of medical and surgical science, especially capable of communicating knowledge, and most punctilious in the discharge of his duties as a teacher. Dr. Rolph died in October, 1870, at the age of 83 years.

Several of the medical professors attached to King's College in 1843, when the medical school was first established, had been members of the old Medical Board, and their work ought to be put upon record, however briefly. Of these Dr. King was professor of medicine and one of the leading medical practitioners of Toronto. Dr. W. C. Gwynne, professor of physiology, was one of three brothers all of whom distinguished themselves. One was judge of the Supreme Court and the other was for many years examiner for the benchers at Osgoode Hall, the Law Courts of Upper Canada. Dr. Henry Sullivan, professor of anatomy and curator of the museum, was a Fellow of the short-lived College of Physicians and Surgeons of Upper Canada. He was younger brother of the late Chief Justice Sullivan. Of Professor Sullivan Dr. Richardson speaks in the highest terms. He was a fine, handsome man and a finished anatomist, most assiduous in discharge of his duties, and greatly beloved by all with whom he came into contact. He died from pulmonary tuberculosis in 1850. Dr. Grant Powell was a member of the Medical Board of 1822. He was born in Norwich, England, in 1779 and died in 1838, and throughout his medical career in the colony was accepted as a leader of scientific thought. Dr. William Warren Baldwin, another member of the Medical Board of 1822, came to Canada from Cork, Ireland, in 1789, and settled in Toronto at a date somewhat later. He died in 1844. He was more distinguished as a barrister than as a medical practitioner.

FIG. 3.

Dr. John Rolph.

Dr. James Henry Richardson, to whom we owe much of this information, was born at Presqu' Ile in 1823. He began his medical studies in 1841 with Dr. John Rolph, then living in Rochester, N.Y., and remained with him for two years In 1844 he went to London and studied at Guy's Hospital for three years. He is said to have been the first Canadian to receive the diploma o the Royal College of Surgeons of England. In 1848 he took the degree of M.B. at King's College, Toronto, and in 185 was appointed to succeed Dr. Henry Sullivan as professor anatomy in the newly constituted medical department of e University of Toronto, having acted as substitute for ofessor Sullivan when the latter was incapacitated from ty by illness. Dr. Richardson held the chair of anatomy in e University until the medical department was abolished 1853, and when the medical faculty was re-organised he as again appointed professor of anatomy. He has been on e staff of the Toronto General Hospital and is an ex-esident of the Ontario Medical Association. Referring to edical practitioners in Toronto prior to 1833 Dr. Richardson the reminiscences with which he assisted us to write these ticles was unable to record anything in regard to their rsonalities, but although he does not remember the dividual practitioners he has vivid recollections of leedings, purgatives, blistering and leeching as he himself 1829 underwent these drastic remedies for the relief of cute rheumatism at that date In the early "thirties" Dr. ichardson was acquainted also with a Dr. Morrison, who as Mayor of "Muddy little York" when its name was hanged to Toronto. Dr. Morrison was tried for high treason or his share in the rebellion of 1838. It was expected that e would be convicted and his life trembled in the balance but the jury after long deliberation brought in a merciful verdict. Dr. Morrison, like Dr Rolph, went to Rochester, N.Y., and remained there until the amnesty.

FIG 4

Dr. James H. Richardson.

Dr. Richardson gave us an amusing sketch of a method of medical treatment in vogue in Toronto in the early "thirties" known as "Thompsonism." It derived its name from one Thompson who published a book on Medicine, the two leading principles of which were—first, that all mineral medicines are poisons, and the second, that "Life is heat and cold is death." His practice was limited to the use of antidotes to "canker," and a few vegetables like lady's slipper (cypripedium) and lobelia. His principal remedies were numbered from 1 to 6. His mainstay he named 6. It consisted of gum, myrrh, cayenne pepper, and brandy. It is interesting to learn that even in the early days of Toronto quackery was more or less rampant and, of course, so far as homœopathy is concerned the practice has far more sway and its followers are far more numerous in the United States and in Canada than in the United Kingdom. (Fig. 4.)

This sketch of the early history of medicine in Upper Canada brings us to the year 1842, when a definite effort was made to establish a medical school in Toronto.

(To be continued.)

Obituary.

JOHN BLACKBURN, M.R.C.S. ENG., L.S.A.

Mr. John Blackburn, a well-known medical practitioner in Barnsley and formerly mayor of that town, died at his residence there on July 7th. Mr. Blackburn, who was in his seventy-third year, had been in failing health for some time and on the Tuesday before his death the guardians had consented to his son, Dr. Ernest W. Blackburn, temporarily taking over his father's duties as medical officer of the first district of the Barnsley union. Mr. Blackburn, who was educated at the Barnsley Grammar School, began his medical work under the late Dr. Jackson of Barnsley, subsequently studying at the Sheffield Medical College and in London. In 1859 he was admitted a Member of the Royal College of Surgeons of England and three years later a Licentiate of the Society of Apothecaries of London. He began practice in Barnsley in 1859 and was soon after appointed medical officer to the Barnsley union, a post which he shared with one colleague. Some years later the districts were re-arranged and Mr. Blackburn was then appointed medical officer and public vaccinator to the town of Barnsley, both of which posts he held until his death.

Mr. Blackburn was a keen Volunteer; he was the holder of the Volunteer Decoration and served at various times as surgeon-major of the 2nd Volunteer Battalion York and Lancaster Regiment and Brigade-Surgeon-Lieutenant-Colonel of the East Yorkshire Volunteer Brigade. In another capacity he did a great deal to popularise ambulance work and was one of the first of the honorary associates of the Order of St. John of Jerusalem. He was for many years on the active staff of the Beckett Hospital and latterly acted as consulting surgeon. His civic connexion with Barnsley began in 1869 when the borough was incorporated. In that year he was elected councillor for the South Ward, in 1884 he became an alderman, and in 1891 he was elected mayor. In 1873 he lost his seat as councillor owing to his having strongly supported the building of swimming baths, to which many ratepayers were opposed. But in the following year he was re-elected and remained councillor until his election as alderman. Besides being surgeon to the Beckett Hospital he was also surgeon to the Midland Railway Company and to the West Riding constabulary.

The funeral took place on July 10th when his body was laid to rest in High Bradfield cemetery. The first part of the Burial Office was said at St. Mary's Church and the remainder at the graveside. The body was escorted to the cemetery by the members of the family and by a large number of representatives of public bodies and institutions in the town with which Mr. Blackburn had been connected. Mr. Blackburn, whose wife predeceased him, leaves three children, one daughter and two sons. Both sons are in the medical profession and in practice at Barnsley.

CHARLES ANGUS, M.B., C.M. ABERD.

Dr. Charles Angus, medical superintendent of Kingseat Asylum, Aberdeenshire, who obtained leave of absence only a short time ago from the Aberdeen Lunacy Board, had been suffering from a serious internal complaint for which an operation became necessary, but in spite of the careful attention of his medical friends his death took place in a nursing home in Aberdeen shortly before 3 o'clock on the morning of July 21st, in his forty-eighth year. At the time of his appointment to Kingseat in March, 1903, Dr. Angus was medical superintendent of the Royal Infirmary, Aberdeen, and he was formerly senior medical assistant at the Aberdeen Royal Lunatic Asylum. While a student in the University of Aberdeen he gained prizes or honorary certificates in most of the medical classes. In 1887 he graduated M B, C.M. After his graduation he was elected senior demonstrator of anatomy. In June, 1889, he was appointed junior resident medical assistant at the Aberdeen Royal Asylum. In March, 1890, he was promoted to the senior assistantship, a post which he held for nearly eight years. During that period he was fortunate in seeing the recent extension of the asylum carried out. He had had altogether ten years' experience in the working of the various departments of an asylum in which about 750 patients were accommodated. On leaving the Aberdeen Royal Asylum he was appointed medical superintendent of the Aberdeen Royal Infirmary and Convalescent Hospital. He continued to make a special study of mental derangement and its treatment in all its bearings and to make a special study also of asylum construction and administration, and amongst other institutions he visited and made himself familiar with the construction and working of the asylum at Altscherlitz in Germany. Dr. W. Reid, the medical superintendent of the asylum, described Dr. Angus as "a man possessed of shrewdness, firmness, and tact, all intermingled with much kindness of heart. He has a complete knowledge of the working and management of a large lunatic asylum in all its details, more especially in regard to the internal economy, *to farming in all its aspects*, to amusing and dealing with patients, a gift which few possess to the *same extent*." Dr. Angus was a native of Rhynie, Aberdeenshire. He leaves a widow and two daughters.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—The following gentlemen passed the examination in Practical Pharmacy held on July 18th and 19th:—

George Aldridge, St. Bartholomew's Hospital; James Appleyard, University College Hospital; David Greig Arthur, St. Bartholomew's Hospital; Raymond Glendour Bingham, St. Thomas's *Hospital*; *Guy Capper Birt*, St. Thomas's *Hospital*; Arthur Ellis Blythman, Sheffield University and Charing Cross Hospital; Ivo Geikie Cobb, St. Thomas's Hospital; Beril Molesworth Collard, London Hospital; James Thomas Daly, L.D.S., Middlesex Hospital; Samuel Danziger, Manchester University; David Henry Davies and William Townsend Dobson, University College, Cardiff; Howard Robinson Elliott, Sheffield University and private; Gordon Ernest Dormer Ellis, St. Bartholomew's Hospital; Daniel Charles Evans, University College, Cardiff; Hugh Arthur Evans, Westminster Hospital and private; Cyril Douglas Faulkner and Edwin George Percival Faulkner, St. Mary's Hospital and private; Hilton Evans Bear Finlaison, St. Mary's Hospital; William Trevor Flooks, Cardiff; Gordon John Gallagher, Liverpool University; Harold Gibson, *London Hospital*; *George Graham, B.A. Cambridge*, Cambridge University and St. Bartholomew's Hospital; Harry Leroy Satterlee Griffiths, University College Cardiff; John Griffiths, Technical College, Swansea; Clifford Hall, Manchester University; Charles Herbert Hart, University College, Bristol; Geoffrey Richard Heard, London *Hospital*; *Thomas Shirley Hele*, B.A. Camb., B.Sc. Lond., Cambridge University and St. Bartholomew's Hospital; Edward Coomber Hobbs and Rowland Augustus Hobbs, St. Mary's Hospital; Francis Harold Holl, Cambridge University and St. Thomas's Hospital; William Henry Hooton and Ernest Howden, Leeds University; David Edward John Stopford Hughes, St. Bartholomew's Hospital; Alfred Herbert James, University College Hospital; Geoffrey Jefferson, Manchester University; Griffith Lewis *Jones, University College, Cardiff*; *Charles Frederick Vivian* Kebbell and William Robert Kilgour, St. Bartholomew's Hospital; Charles Haley Knowles and John Murgatroyd Land, Leeds University; Martyn Henry Langford, Middlesex Hospital; William Bertram Lawrence, University College, Cardiff; Septimus Joseph Lee, Middlesex Hospital; Edward Claude Linton, London Hospital; Donald McCully, University College; Colin McIver, Madras and University College Hospital; Henry Sinclair Mason, St. *Mary's Hospital* and private; Albert Ernest Moore, London Hospital; Claude Woodham Morris, University College Hospital; Alfred Philip Nicolle and Hubert Lewis Clifford Noel, London Hospital; Charles Noon, St. Bartholomew's Hospital; Robert Sydney Overton, King's College and St. Thomas's Hospitals; Georg Natanael Palmaer, London Hospital; Richard Alfred Parsons, St. Mary's Hospital; Stuart Kingsley Poole, Guy's Hospital; James Freer Richardson, *London Hospital* and private; *Hugh Rimington, St. Bartholomew's* Hospital; Thomas Stanley Rippon, University College, Bristol; Horatio Nelson Ritchie, Sheffield University and private; John Selfe, St. George's *Hospital*; Edgar Arthur Shirvell, London Hospital and private; Oliver Thomas Slatter, M.R.C.S., Guy's Hospital; Harry Stobie, Charing Cross and St. Thomas's Hospitals; Reginald Woolsey Stocks and Thomas Edmund Alexander Stowell, St. Thomas's Hospital; Charles Henry Burton Thompson, Middlesex Hospital; *George Gilbert Timpson, L.D.S., Guy's* Hospital and private; Walter Vincent Tothill, London Hospital; Arthur John Tozer, St. Mary's Hospital; Hugh Bevan Walker, London Hospital and private; Alexander Watson, London Hospital; John Ernest Price Watts, Westminster Hospital and private; Frederick Cecil Wright, St. Bartholomew's Hospital; and Raphael Yood, Manchester University.

UNIVERSITY OF LONDON.—At the examination for the M.D. degree held recently the following candidates satisfied the examiners:—

Medicine.—John Hunter Clatworthy, Guy's Hospital; Fred Claude Bromley Gittings, Middlesex Hospital; Louisa Hamilton, B.S., London (Royal Free Hospital) School *of Medicine for Women*; Harold Charles Voughton Knight, St. Bartholomew's Hospital; Harold Charles *Corry* Mann, B.S., and Edwin Henry Britton Milsom, Guy's Hospital; Edgar Coningsby Myott, B.S., Guy's *Hospital* and Victoria University; Thomas Perrin, B.S., St. Thomas's Hospital; Harold Pritchard, B.S., St. Bartholomew's Hospital; William Arthur Rees, Middlesex Hospital; George Herbert Sowry, B.S., St. Bartholomew's Hospital; Henry Francis Bell Walker, Guy's Hospital; and Howard Edward Wise, Middlesex Hospital.

Mental Diseases and Psychology.—Gayton Warwick Smith, Guy's Hospital.

Midwifery and Diseases of Women.—George Ernest Aubrey, B.S., St. Bartholomew's Hospital; Lucian A. E. de Zilwa, B.Sc., University College; *Llewellyn S. H. Glanville*, B.S., Guy's Hospital; William Percy Gowland, B.S., Victoria University; Ernest Charles Mackay, B.S., St. Bartholomew's Hospital; Harold Farley Seymour, London Hospital; Frank Edward Taylor, B.S., University of Leeds and King's College; Ernest Frank Travers and Vere [illegible] Ward, St. Bartholomew's Hospital; and *Florence E. Willey*, M.S., B.Sc., London (Royal Free Hospital) School of Medicine for Women.

State Medicine.—Morgan James Rees, Guy's Hospital.

Tropical Medicine.—Frederick Norman White, St. Bartholomew's Hospital and London School of Tropical Medicine.

N.B.—This list, published for the convenience of candidates, is issued subject to its approval by the Senate.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held in July the following candidates passed in the subjects indicated:—

Surgery.—J. L. Meynell (Section II.), London Hospital; E. Sutcliffe (Section I.), Leeds; E. J. F. Thomas (Section II.), Middlesex Hospital; and G. L. Walker (Sections I. and II.), Leeds.

Medicine.—A. C. J. Elwin (Sections I. and II.), King's College Hospital; E. Gay (Section II.), Lausanne; H. J. May (Sections I. and II.), London Hospital; J. L. Meynell (Section II.), London Hospital; E. Moir (Sections I. and II.), Manchester; L. Nicholls (Section I.), Cambridge and London Hospital; A. F. [illegible] (Section I.), St. Bartholomew's *Hospital*; *A. Sheppard* (Sections I. and II.), Guy's Hospital; E. W. Squire (Sections I. and II.), St. Mary's Hospital; E. J. F. Thomas (Section II.), Middlesex Hospital; and W. H. Williams (Section I.), St. Bartholomew's Hospital.

Forensic Medicine.—E. V. Connellan, Bristol; A. C. J. Elwin, King's *College Hospital*; W. H. *Lister*, Durham; E. Morris, St. Bartholomew's Hospital; L. Nicholls, Cambridge and London Hospital; A. Sheppard, Guy's Hospital; E. W. Squire, St. Mary's Hospital; F. A. K. Stuart, Cambridge and St. Mary's Hospital; and W. H. Williams, St. Bartholomew's Hospital.

Midwifery.—E. R. Bastard, St. Bartholomew's Hospital; E. S. [illegible], Royal Free Hospital; G. B. Messenger, Westminster Hospital; L. Nicholls, Cambridge and London Hospital; and P. D. [illegible], *Leeds.*

The diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery:—H. J. May, J. L. Meynell, E. Morris, and E. J. F. Thomas.

UNIVERSITY OF GLASGOW.—The following degrees were conferred on July 17th:—

Doctors of Medicine (M.D.).—Commendation: Madge [illegible] Maclean, M.B., C.M., Scotland. Ordinary degree: John [illegible], M.B., C.M., Scotland; John Andrew Cook, M.B., C.M., Scotland; Daniel Ferguson, M.B., C.M., Scotland; and John Selkirk, M.A., M.B., C.M., Scotland.

Bachelor of Medicine and Master in Surgery (M.B., C.M.).—Honours: Robert Stewart M'Kim, M.A., Scotland.

Bachelors of Medicine and Bachelors of Surgery (M.B., Ch.B.).—*Honours*: **Peter Mitchell*, M.A., Scotland; and John Stevenson, Scotland. Commendation: William Rome Cammock, Scotland; George Haswell Wilson, England; James M'Farlane, Scotland; Thomas Baillie Smith, Scotland; James Richan Drever, M.A., Scotland; Elizabeth Maud M'Vail, Scotland; William James Rutherfurd, Scotland; and William Gilfillan, Scotland. Ordinary degrees: John Anderson, M.A., B.Sc., Scotland; Thomas Barbour, M.A., B.Sc., Scotland; George Duncan Morrison *Beaton, Scotland*; *Charles Burns, Scotland*; John Miller [illegible] Caldwell, Scotland; George Campbell, Scotland; William Archibald Campbell, Scotland; Henry Howard Christie, New Zealand; John Sawers Clark, M.A., Scotland; *James* Coutts, Scotland; Thomas Lawson *Craig*, Scotland; Arthur Muir Crawford, Scotland; Ernest Milne Eaton, Scotland; William Gilbert, Scotland; Arnold Harris Gray, Scotland; Robert Neil Guthrie, New Zealand; Charles Francis Dyer Hammond, England; William Towers Hardie, *Scotland*; *Robert* M'Cowan Hill, Scotland; Alexander Hunter, Scotland; Archibald Yuill Hutchison, Scotland; John Keys, Scotland; James Dunlop Kidd, Scotland; William Hendrie Kirk, Scotland; Alexander M'Call, Scotland; Thomas M'Cririck, M.A., B.Sc., Scotland; David MacDonald, Scotland; John Robert M'Gilvray, Scotland; William Anderson M'Kellar, Scotland; William Ferguson Mackenzie, Scotland; Norman Smith MacNaughtan, Scotland; Alister *Argyle Campbell* M'Neill, Scotland; Andrew Alexander M'Whan, Scotland; Florence Mann, Scotland; William [illegible] Manson, M.A., Scotland; Robert Marshall, Scotland; John Miller, Scotland; William Miller, *Scotland*; *Edith Oversby*, England; James Hogg Paul, Scotland; Agnes Picken, M.A., Scotland; Alexander MacMillan Pollock, Scotland; Thomas Hood Rankin, Scotland; Vera Dagmar Reis, Ireland; Frederick [illegible] Robertson, Scotland; William Hermann Sieger, Scotland; William Smellie, Scotland; James Stevenson, Scotland; David Laurence Tate, Jamaica; Charles Samson Thomson, Scotland; James Wyper, Scotland; *John Young (Mount Vernon), Scotland; and Morris *Youdelevitz Young*, Syria.

* Dr. Mitchell gains the Brunton memorial prize of £10, awarded to the most distinguished graduate in medicine in the year.

KING'S COLLEGE, LONDON.—A class in experimental psychology, including practical work and demonstrations, will be held by Professor C. S. Myers on Saturdays at 11 A.M., in the Psychological Laboratory of the College. The class will first meet on Oct. 6th, at noon, and those who wish to attend are requested to apply to Professor Myers at Melrose, Grange-road, Cambridge. A course of lectures on General Psychology will also be given by Professor Myers *during the October session* on Wednesdays at 2 P.M.; these lectures will be repeated on Fridays at

3.30 P.M. Further particulars may be obtained from the Secretary at King's College.

Public Health in Madeira.—Mr. Edward Vicars, the British Consul at Madeira, in his report for 1905, received at the Foreign Office on May 26th, states that the health statistics for the year were good, showing considerable improvement on those for the two previous years. The total number of deaths from all causes in Funchal amounted to 1041 out of a population of 43,375, as against 1258 in 1904 and 1531 in 1903, or at the rate of 35·2, 29, and 24 per 1000 in the three successive years. The death-rate on the population of the whole island—150,574 (of whom no less than 135,580 are illiterates)—was, if the statistics are correct, only 22·5 per 1000. There was no further outbreak of typhoid fever, such as caused so much alarm in 1903 and 1904, the deaths from that disease being only 16, as against 47 and 59 recorded in those two years. It is to be hoped, however, remarks Mr. Vicars, that this comparative immunity from the malady will not serve to lull the authorities into a false feeling of security and thereby cause them to postpone the carrying out of a proper system of drainage and the establishment of a trustworthy water-supply, both of which are urgently needed. In regard to an alarm of plague which had a crippling effect on the business of the port during the closing week of the year, the Consul observes: "This would not be the place, even were the matter not now the subject of a judicial inquiry, to discuss the question in all its bearings, but I may perhaps be permitted to say that the action of the mob who finally stormed the lazaretto and liberated the so-called 'plague' patients proved beyond all question that no plague existed, for no outbreak of that or any other disease followed the rescue of the inmates and their restoration to their homes as must inevitably have happened had they been suffering from a highly infectious malady On the contrary, they one and all proceeded to recover. The annexed statistics of the deaths in Funchal and its neighbouring parishes during the winter months of the last three years afford the most eloquent commentary on the genuineness of this unfortunate scare, which, besides paralysing the business of the port, has been responsible for one of the worst visitors' seasons of recent years:—

Deaths in Conchello of Funchal during Winters of 1903-04 to 1905-06.

	1903-04.	1904-05.	1905-06
November	145	73	76
December	151	100	95
January	142	80	71

These figures speak for themselves. The 1904–05 returns were normal, those for 1903–04 having been greatly swelled by the severe epidemic of typhoid to which I have already referred. The number of deaths of British subjects in Madeira during 1905 was 14, but this figure bears no relation to the mortality among the permanent British colony (numbering 270), as many of those who die here are either visitors or British seamen left behind in the Seamen's Hospital."

Literary Intelligence.—We learn that the twelfth edition of the Extra Pharmacopœia of Martindale and Westcott will be published about the middle of August. It is stated that the text has been rearranged for more ready reference and that additions have been made taken from current literature and from many recent standard works, especially various national Pharmacopœias. A new feature in the work is the appearance of chemical formulæ for all bodies to which a definite chemical constitution could be attributed. The molecular weights of these bodies have been calculated in terms of the British Pharmacopœia equivalents, those of the International Atomic Weights, 1906, and in terms of the United States Pharmacopœia. Greater prominence has been accorded to dental therapeutics. Antitoxins and serum therapy have been brought up to date in the light of the most recent researches, theories, and trials. The sections on radiology, clinical analysis, bacteriology, and the therapeutic index have similarly been thoroughly revised. The work contains over 350 pages more than the eleventh edition but the book remains even now of a size which can be conveniently carried in the pocket of the physician or the chemist. In the section on organotherapy preparations of the duodenal membrane, suprarenal and thyroid glands, and the method of treatment by the inspissated milk of thyroidectomised animals have received careful attention; under the heading antitoxins, vaccines, and antitoxic serums the subjects of anthrax (Sclavo's serum), malaria, leprosy, plague, cancer, tetanus, trypanosomiasis, tuberculin, vaccine, &c., have all been brought up to date in the light of the most recent researches; the latest views on opsonins are described.

Queen Charlotte's Lying-in Hospital.—The clinical report of Queen Charlotte's Lying-in Hospital for 1905 states that during the year ending Dec 31st there were 1544 in-patients discharged after delivery, 930 being primiparæ and 614 being multiparæ. The average duration of stay in the hospital was 14 days. There were five maternal deaths, all in multiparæ, of ages from 33 to 45 years, the causes being placenta prævia, septicæmia, peritonitis, anuria, and accidental hæmorrhage. Forceps were used to deliver the forecoming head in 144 cases, giving a forceps-rate for the year of 9·3 per cent. Of these patients 18 were multiparæ, the remainder being primiparæ; all made good recoveries, except one primipara who suffered from eclampsia, septic endometritis, and pulmonary embolism, but in the result she recovered completely. Uterine inertia and persistent occipito-posterior positions were the two commonest indications for forceps. The youngest and oldest patients for whom forceps were used were 14 and 46 years of age respectively. Version was performed in 17 cases, in ten of which the shoulder presented. Contracted pelvis was found in 61 patients. Women seeking admission to the hospital are generally seen about eight weeks before term; primigravidæ then have their pelves measured and multigravidæ who have had previous obstetric trouble are also examined. Spontaneous delivery occurred in 14 of these cases; 17 were treated by induction of premature labour, nine by Cæsarean section, 18 by forceps, and six by version. Eclampsia occurred in six patients, all of whom recovered; the report makes special mention of the good effects of intravenous injections of normal saline solution in this condition.

Manchester Housing and Health.—A memorial from the Manchester and Salford Sanitary Association was recently presented to Sir Thomas T. Shann who received it on behalf of the Lord Mayor of Manchester who was unable to be present. The memorial urged that it was necessary for the proper guarding of health of the citizens of the future that town councils should have more extended powers of buying and laying out land in the neighbourhood of our towns and that they should have, and use, the power of making plans for all land not built on, and near the towns, which must be complied with, such plans to arrange for the width and direction of the streets and the number and size of the open spaces. The memorialists approved a suggestion of the social questions committee that there should be a conference of local authorities for the purpose of agreeing, if possible, on a definite plan of laying out intermediate areas not now built on so as to insure better housing conditions for the future. Dr. W. E Sawers-Scott spoke of the damage done in the past by the lack of system in laying out our cities and by the builders building at their sweet will. He was followed by Mr. T. C. Horsfall, who said their object was to ask town councils to put a stop to an overwhelming evil. Over 77 per cent. of our population live in the towns and only 23 per cent. in the country. In the past the country population had been drawn upon to make good the waste of the towns but now there was not a sufficient balance in the *country* to do that. If we were to have a strong and vigorous race the towns must be made healthy. In the central districts of the city the conditions were such as to make health impossible. He spoke also of the formation of slums now going on in the suburbs and the steady reproduction of all the evils of the congested centres, "because building was not carried out under any well-defined plan drawn up by a central intelligent authority." Other members of the deputation addressed Sir Thomas Shann and Dr. A. Emrys Jones spoke of the danger that the Platt Hall estate might fall into the hands of the jerry builder. Sir Thomas Shann thanked the deputation and dismissed it with a sympathetic, non-committal answer.

The Children's Sanatorium for the Treatment of Phthisis, Holt, Norfolk.—As we have already pointed out (*vide* THE LANCET of June 16th, p. 1728), arrangements have been made for the accommodation of 12 children in a temporary home adjoining the site of the Children's Sanatorium at Holt, Norfolk, pending the erection of the permanent building. We are now informed that applicants must be suffering from the early stages of pulmonary tuberculosis and the age limit is—for girls, from two to 16 years of age; and for boys, from two to ten years. The terms are 25*s.* a week inclusive. Assistance, so far as funds admit, will be given to necessitous children recommended by the Invalid Children's Aid Association, but in all other cases the full cost must be guaranteed before admission. The Invalid Children's Aid Association, 69, *Denison House, Vauxhall Bridge-road*, Victoria, S.W., will provide for the investigation and medical inspection of all cases and forms can be obtained from the secretary. Meanwhile, in addition to donations for the building fund, the committee appeals earnestly for annual subscriptions to provide for the maintenance of children about to be received. Such donations or subscriptions may be paid to the bankers, Messrs. Hoare and Co., 37, Fleet-street, London, E.C., or to the honorary secretary of the Children's Sanatorium, whose address is 68, Denison House, Vauxhall Bridge-road, Victoria, London, S.W.

DONATIONS AND BEQUESTS.—By the will of the late Dr. James Stewart a sum of over £25,000 is left to the president and council of the University of Melbourne, Victoria, to found and endow in perpetuity three scholarships, each of an annual value of not more than £50, and tenable at the discretion of the president and council for two or three years, to be called the "Stewart Scholarships," one to be awarded for anatomy, one for medicine, and one for surgery.

MEDICAL MAGISTRATE.—Mr. W. Muir Smith, M.B., C.M. Glasg., has been appointed a justice of the peace for Eastbourne.

CENTENARIANS.—Miss Margaret Evans of Pontneath, Glamorganshire, died on July 12th in her 102nd year.—Mr. James Glass died at Graig, Llansadwrn, South Wales, on July 14th. The deceased was a native of Carmarthen, and from the records obtained from St. Peter's Church in that town it was ascertained that he was born on May 1st, 1802.—The death of a native chief, Sigananda, at Nkandhla, in South Africa, is reported. His age was stated to be 104 years.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Bills Abandoned.

IN the last few days a large number of Bills promoted by private Members have been "dropped," to use the Parliamentary expression. Among these are the following measures: Coroners (Mr. LUKE WHITE); Education of the Blind (Mr. STEADMAN); Juvenile Smoking (Dr. MACNAMARA); Nurses' Registration (Mr. MUNRO FERGUSON); Pharmacy (Mr. WINFREY); Public Health (Sir JAMES WOODHOUSE); Public Health Officers (Sir FRANCIS POWELL); and Abolition of Vivisection (Mr. JOHN JOHNSON).

HOUSE OF COMMONS.

FRIDAY, JULY 20TH.

Defective Eyesight of Children.

Mr. BARNES asked the President of the Board of Education whether the promised amendment to the 35th clause of the Education Bill dealing with medical inspection would include a provision authorising local authorities to provide glasses for such children as were found to be of defective eyesight.—Mr. BIRRELL answered: The amendment which the Government inserted in the clause dealt only with medical inspection, which was made compulsory. The point referred to in the honourable Member's question would therefore not fall within it but would come, if at all, within the remainder of paragraph (b) of Clause 35. On this I have to say that I am not prepared to give a general interpretation beforehand as to the various individual matters which would fall within the powers of a local authority under the term "such arrangements as may be sanctioned by the Board of Education pertaining to the health and physical condition of the children educated in the public elementary schools," since the clause throws upon the Board the duty of giving hereafter such sanction as it may think justified by the circumstances of each individual case.

The Gordon College, Khartoum.

Mr. GEORGE GREENWOOD asked the Secretary of State for Foreign Affairs whether his attention had been called to a series of vivisectional experiments performed on dogs, monkeys, and other animals by Andrew Balfour, M.D., at the Wellcome Research Laboratories, Gordon College, Khartoum; whether the Gordon College was under British control; whether the Wellcome Research Laboratories formed part of such college or what was their connexion with it; how such laboratories were maintained and whether or not by public money; whether vivisectional experiments were habitually performed at the Gordon College; whether the operators were subject to any inspection, regulation, or control; and whether such practice was sanctioned by the British Government or its representative in Egypt.—Sir EDWARD GREY replied: I have no information on the points mentioned in the question but I will make inquiries on the subject. The Gordon College at Khartoum is not under the control of the Foreign Office.

TUESDAY, JULY 24TH.

Central Midwives Board and Irish Midwives.

Mr. HEALY asked the Under Secretary of State for the Colonies whether his attention had been called to the injury resulting to the high reputation in obstetric knowledge enjoyed by qualified Irish midwives through the insertion in colonial official advertisements of the requirement that the new certificate legalised in England for the first time in 1902 was a *sine quâ non*; whether he would inquire if pledges were given in the House when the Midwives Act, 1902, was allowed to pass to the effect that *the much older Irish* qualifications would not be prejudiced; and whether he would then inform the colonial Government of the facts, and that after the passing of the Midwives Act the new English Board refused its certificate to *qualified Irish midwives* unless they came to England and passed its examinations, involving more than ten days' absence from home and heavy expense.—Mr. CHURCHILL answered: I fear I have no knowledge of the circumstances referred to in my honourable friend's question. I gather from it that some of the colonies are following a certain rule or practice laid down in England and it seems to me that whatever exception is taken should be to that rule or practice and that the Secretary of State can hardly instruct or advise the colonies not to follow it as long as it exists in this country.

Mr. HEALY asked the Secretary of State for the Home Department whether he was aware that the Midwives Act as at present administered by the Central Midwives Board was being employed as a means of preventing Irish midwives from practising in England, although when the Act was passed Irish representatives were given a distinct guarantee by the promoter that nurses trained in the Irish maternity hospitals would be in no way affected by it; would he inquire whether it was the fact that fully trained and certificated Irish hospital midwives had now to cross over to England and spend ten days in the country in order to pass the qualifying examination of the Central Midwives Board and that but few nurses could spare the time *and money to do this; whether the Central Midwives* Board had refused to allow examinations to be held in Ireland, though the *Irish Midwives Association had guaranteed to defray* the expenses of the same; and whether he was aware that colonial authorities were advertising that the English Central Midwives Board's certificate must be possessed by midwives seeking appointments in the colonies, thus excluding women with Irish qualifications.—Mr. GLADSTONE answered: I am not aware that the Central Midwives Board is taking any such action as is suggested in the first part of the question. The Midwives Act, 1902, does not apply to Scotland or Ireland, but my right honourable friend the Lord President of the Council informs me that the Central Midwives Board has never refused to recognise the Irish midwifery qualifications. During the operation of Section 2 of the Act three Irish midwifery qualifications, in addition to the three mentioned in the Act, were recognised by the Board as entitling their holders to claim the benefits of that section. As to the question of the holding of examinations in Ireland, the Central *Midwives Board considers it has no power to conduct* examinations except at centres in England and Wales, but the Lord President of the Council is taking the opinion of the law officers of the Crown upon the legal point involved. No such advertisements as those to which the honourable Member refers in the last sentence of his question have been brought to my notice.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

DENNING, F. A. V., L.R.C.P. Edin., L.R.C.S. Irel., has been appointed Certifying Surgeon under the Factory and Workshop Act for the Sligo District of the county of Sligo.

ESKELL, L. B., L.D.S., R.C.S.I., has been appointed Honorary Dental Surgeon to the Winsley Sanatorium for the Consumptives of the Counties of Gloucester, Somerset, and Wiltshire, and the City and County of Bristol.

GOODE, CHRISTINA L., M.B., B.S. Melb., has been appointed Assistant Medical Superintendent to the Leytonstone Infirmary.

KERRAWALLA, M. P., M.D. Brux., L.R.C.P. & S. Edin., L.M. & S., has been appointed *Assistant House Surgeon to the* Hastings, St. Leonards, and East Sussex Hospital.

MOULD, G. T., Major, I.M.S. (retired), has been appointed Refraction Assistant at the Royal London Ophthalmic Hospital (Moorfields Eye Hospital).

NOALL, W. PAYNTER, M.S. Lond., F.R.C.S. Eng., has been appointed Clinical Assistant to the Chelsea Hospital for Women.

PORTER, CHARLES, M.D. Edin., has been appointed Assistant Medical Officer of Health of Leeds.

WALKER, THOMAS WARBURTON, M.B., Ch.B. Vict., has been appointed Medical Officer to the Workhouse by the Tetbury (Gloucestershire) Board of Guardians.

WATSON, GEORGE W., M.D., M.R.C.P. Lond., has been appointed Honorary Demonstrator of Medicine in the University of Leeds.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

BRACEBRIDGE ASYLUM, Lincolnshire.—Senior Assistant Medical Officer, unmarried. Salary £150 per annum, with apartments, board, attendance, and washing.

oen, Royal Infirmary.—Medical Officer, unmarried. Salary 00 per annum, with board and residence.

ton, Sussex County Hospital.—House Physician, unmarried. lary £70 per annum, with board and residence.

ton Throat and Ear Hospital, Church-street, Queen's-road.—n-resident House Surgeon for six months, renewable. Salary at te of £75 per annum.

ton and Manchester Joint Colony for Epileptics, Langho, ar Blackburn.—Resident Medical Officer. Salary £150 per annum, th board and residence.

ester, Essex and Colchester General Hospital.—House ysician. Salary £80 per annum, with board, residence, and ashing. Also House Surgeon. Salary £80 per annum, with ard, washing, and residence.

nport, Royal Albert Hospital.—Assistant Resident Medical ficer, unmarried, for six months. Salary at rate of £50 a year, th board and lodging.

tian Government, Ministry of Education.—Professor of Mid-fery and Gynæcology. Salary £400 a year. Also Medical Tutor d Registrar to Kasr-el-Ainy Hospital. Salary £400 a year.

ina Hospital for Sick Children, Southwark Bridge-road, S.E. -Physician to Out-patients.

ital for Epilepsy and Paralysis and other Diseases of he Nervous System, Maida Vale, W.—Anæsthetist.

s, Hospital for Women and Children.—Resident Clinical sistant for three months.

all Fever Hospital, Manchester.—Fourth Medical Assistant. lary £100 per annum, with board, lodging, and washing.

nt Vernon Hospital for Consumption and Diseases of the hest, Hampstead and Northwood.—Resident Medical Officer. alary £50 per annum, with board, lodging, &c.

h-Eastern Hospital for Children, Hackney-road, Bethnal reen, E.—Medical Officer in charge of Electrical Department. alary £50 per annum.

ton Royal Infirmary.—Senior House Surgeon. Salary £100 per nnum, with board, lodging, washing, &c.

n Charlotte's Lying-in Hospital, Marylebone-road, N.W.—hysician to Out-patients.

al Hospital for Diseases of the Chest, City-road, E.C.—House Physician for four weeks.

field Union Hospital.—Resident Medical Officer. Salary £100 er annum, with apartments, rations, and allowances.

rran (Ancient) Hospital, near Durham.—Medical Officer. alary £100, with house, coals, &c.

kport Infirmary.—Junior Assistant House Surgeon for six months. Salary at rate of £40 per annum, with board, washing, and residence.

derland Infirmary.—Two House Surgeons. Salary £80 per annum, with board, residence, and washing.

t Bromwich District Hospital.—House Surgeon, unmarried. Salary £100 per annum, with board, residence, and washing.

ton-super-Mare Hospital.—House Surgeon, unmarried. Salary £100 per annum, with board and residence.

ech, North Cambridgeshire Hospital.—Resident Medical Officer.

verhampton and Staffordshire General Hospital.—Assistant House Surgeon, for six months. Honorarium at rate of £75 per annum, with board, lodging, and washing.

Births, Marriages, and Deaths.

BIRTH.

ter.—At Ingledean, Ilkeston, the wife of W. H. St. Leger Carter, L.R.C.P., L.R.C.S.E., of a son.

MARRIAGES.

ziel—Wilson.—On July 21st, at the parish church, Forest Row, Captain R. M. Dalziel, I.M.S., to Euphemia Beattie (Effie), only daughter of Arthur Ross Wilson, Esq., Almora, India.

ff-Hewitt—Hannah.—On July 18th, by licence, at the parish church, Ashton-in-Makerfield, by the Rev. W. Williams, rector of Holy Trinity, assisted by the Rev. F. Kennen, curate-in-charge St. Luke's, William E. Huff-Hewitt, M.B., Ch.B., Rhis-on-Sea, younger son of the late Rev. W. J. Hewitt, to Maud Elizabeth, second daughter of Nathan Hannah, L.R.C.P. Edin., M.O.H., &c., of Rock House, Ashton-in-Makerfield. "At home" Sept. 12th and 13th.

llar—Graham.—At Durban, South Africa, on the 15th June, James Grant Millar, M.B., Ch.B., youngest son of the Rev. David Millar, D.D., of St. John's, Glasgow, to Mary Lang, second daughter of the late Andrew Lang Graham and Mrs. Graham, 12, Park-circus, Glasgow.

DEATHS.

rcan.—On July 22nd, at Grosvenor-road, Highbury, N., Andrew David Duncan, M.D. Edin., L.R.C.S. Edin., aged 67.

ardson.—On July 20th, at the Friary, Winchester, Richard Margerison, B.A., F.R.C.S., aged 54.

ble Smith.—On July 20th, at Queen Anne-street, Cavendish-square, Noble Smith, F.R.C.S. Edin., in his 60th year.

ing.—On July 15th, at Wellington, New Zealand, Charles Edward Wing, L.R.C.P., M.R.C.S., younger son of the late Henry Wing, surgeon, Bury St. Edmunds.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

THE HUMOURS OF COUNTRY PRACTICE.

"The art of medicine, like most other things, has its humorous side, and the following extracts from the notes of 18 years' country practice may amuse your readers. It is well that the lighter side of work which must often be so sombre should now and then be viewed. Each extract is absolutely authentic and none is 'touched up' in any way." Thus writes an esteemed correspondent in preface to the following amusing notes of his daily life:—

To begin with an artless consultation in the surgery. Enter two small children, the elder of whom, aged about six years, produces a flat pint bottle, of the sort in which the best pale brandy is dispensed to the public, and says, "Please, some medicine for the baby." "Well, what's the matter with it?" "Please, its got a bad backside." I wonder how Sir William Broadbent or Sir Richard Douglas Powell, or any other of our revered leaders, would deal with a medical emergency such as this? Would they be more competent than the humble G.P.? Small wonder, by-the-bye, that Sherlock Holmes was evolved by a medical man; there is a deal of deduction goes on in a country surgery.

Then comes a recollection of a cadaverous individual who walks in and with sepulchral tone says, "Good afternoon, sir, I've come to tell you about my stomach, sir. Last Friday it come right up into my throat." What a case for Messrs. Moynihan, Mayo, Ward, and Littlewood! This is one of the patients who seeks to impress you by vivid description of his symptoms. How well we all know him, and how very graphic he can be. Here are some similar efforts enlivening my notebook: "I coughed last night till a lump come in my lenk [groin] and my eyes they struck fire." "When I was eleven year old I 'ad the dynasty; I 'ad the dynasty 'n I 'ad the small-pox, one arter the other." "The itching and aching in my legs, oh, it's somethin' chronic: it makes my eyes strike fire every time my stockins is pulled on (or off)."

Many patients are excessively genteel in talking of matters medical. One good lady, describing a common digestive disturbance, said in a tone of indescribable refinement, "I fancy, Doctor, that a cold was the instigation of it." On another occasion the same lady assured me that she "never was in such a dialeema." Of the same category is the gentleman who approached me delicately with, "I wish to solicit your custom, sir, for my wife in her confinement."

Among odds and ends I find the following. A small girl of about seven, who says mysteriously, "Please, sir, pappa says he's very cautiously in his bowels." Wise man, that. A man, in reply to the inevitable, "How do your bowels act?" replied, "Well, sir, not very gay, sir." (This I have heard so frequently since I first noted it that it has ceased to amuse me and the same is true of the reply: "I'm always rather caustic," which is an almost daily commonplace.) Finally, a virtuous lady, discussing a delinquent neighbour, said: "I don't 'old with such drunkenness and immortality."

Written communications have often relieved the burden of the day's work and as *litera scripta manet* I inclose the originals of all those given below. To begin with a typical one:—"Doctor ——, Sir, I write to inform you that Mrs. B. is very ill, she as a very Bad cold, and cough, her inside seems very week indeed, my water is bad and high colour. I remain, your's truly, Mrs. B."

Here is another sample: "Please, sir, will you be kind enough to try and send Misis R. something to ease her cough and her breath the wind creates round her stomach and she cant get anything to move it at all and it makes her that she cant get about at all, and she will be much obliged if you will do so." That fine expression, "the wind creates round her stomach," has become a classic in our family circle.

Again: "Dear Sir, I write to tell you that Mrs. S. is suffering with pains, it begun in the hipe and as made its way into the back and about folloWing with sickness with flotering in the art and unable to eat and drink. I am, etc., on behalf of Mrs. S., John S."

The following gives the most elaborate rendering of that awkward word diarrhœa. The variations run in this part of the country, from "diaborria," through "direar" and "diare," to the simple form "dyre." "Dear Sir, The Mediceen you sent have stopped the diaborria but I feal very low and weak and I have a pain in my side just to the right of the nable and my nable his larger than it ought to be, yours truly, W. P."

The writer of the following has ingeniously avoided the diarrhœa difficulty:—"Sir, I want you to please to send me some medicine. I have a violent pain in my bowels with pergin, please to send me something to ease the pain."

The genteel letter-writer, of course, flourishes. "Will Dr. —— please note his services will be required as usual at Mrs. H.'s approaching confinement. The event is expected in March, and oblige." And in the following year a postscript:—"And please note that Mrs. H. will require Dr. ——'s services early in September for confinement purposes, as before." And, finally:—"Will Dr. —— kindly lend Mrs. G. the Enema, as Nurse O. wants to give an ejection."

THE EBBW VALE WORKMEN'S DOCTORS' FUND.

THE relations between the working men of Ebbw Vale and the medical officers attending them have reached an acute stage. The workmen's committee has given its medical officers three months' notice to terminate their engagements, and it is stated that steps are to be taken to fill the vacancies thus formed. The anger of the workmen seems to have been aroused chiefly by a letter which appeared in THE LANCET, Dec. 23rd, 1905, p. 1877. This letter, which was from Mr. H. S. Elworthy, one of the medical officers in question, dealt at length and in general terms with the evils arising from the contract system of medical attendance. Ebbw Vale was not mentioned, nor, indeed, was any other locality, and with the statements therein contained we are mainly in agreement. The workers of Ebbw Vale, forgetting the old saw, "If the cap fits put it on," applied Mr. Elworthy's strictures to themselves and accordingly a meeting was arranged and was recently held at which Mr. Elworthy consented to meet the workmen of Ebbw Vale and to discuss the statements contained in his letter. He received a fair hearing but he was much heckled, and Mr. Richards, M.P. for West Monmouthshire, had the bad taste to characterise Mr. Elworthy's statements as "lies, lies, lies." Mr. Richards also made rude remarks as to Mr. Elworthy's conduct in receiving a salary from the Ebbw Vale Colliery Company. Mr. Richards also said "that they would never submit to the British Medical Association" and it was finally decided to publish Mr. Elworthy's name as "the offending doctor." Mr. Elworthy allowed that he might have exaggerated when he said that "patients were in the main highly paid workmen" and that he should have said "in too many cases" instead of "in the main." The rest of his remarks he considered to be substantially correct and he refused to withdraw his statements, as the meeting demanded that he should do.

We consider that Mr. Elworthy is perfectly in the right. He made general statements which are generally true. Ebbw Vale was not mentioned but we make no doubt that the conditions of contract medical practice there are just as bad as anywhere else, and how bad that is those of our readers who remember "The Battle of the Clubs" will have no difficulty in recalling. It has been decided by the Trades and Labour Council of Ebbw Vale to hold a meeting on July 28th at which the subject of the letter will come up.

A QUESTION OF PROFESSIONAL BEHAVIOUR.

To the Editors of THE LANCET.

SIRS,—Recently a patient of mine met with an accident. He went to a neighbouring hospital and was attended by a surgeon on the staff of that hospital, who arranged to see him the next day at his (the surgeon's) own house. He continued to attend him until he was well. Is it in accordance with medical etiquette and gentlemanly conduct for a surgeon to do this, when he knew that the patient had a medical man who was in the habit of attending him? I think the question most important, as it is not the first time that a similar thing has occurred within my own knowledge, and it does not seem to me consistent with the best traditions of our profession.

I am, Sirs, yours faithfully,

July 21st, 1906. INQUIRER.

*** "Inquirer" must know that he has described a bad breach of professional manners.—ED. L.

CIRCUMCISION IN ETHNOGRAPHY.

WE have received a little pamphlet containing a paper upon the ethnography of circumcision, reprinted from the *New York Medical Record* of June 9th. The author of the paper is Dr. John Knott of Dublin who is well known as a writer upon various antiquarian subjects in medicine. The paper is, as Dr. Knott himself terms it, a somewhat "crude panoramic sketch" but for all that it contains materials for a much fuller work on the subject. Circumcision is a custom which is of wide interest to anthropologists. It, or variants of it, such as the arilthakuma of the Central Australian tribes, which, by the way, Dr. Knott does not mention, is a custom found all over the world. The Jewish race, as is well known, regarded the rite as something peculiar to themselves and as marking them off from other nations, and as a matter of fact it did mark them off from most of the known nations of the old world except the Egyptians. So much so was this the case that the writer of the Maccabees complains bitterly that the advanced Jews of the time of that book were so anxious not to appear too national that they made themselves prepuces (ἀκροβυστίας). Unfortunately, he has left no record of how this interesting prosthesis was carried out. Circumcision in boys and the analogous rite in girls have been performed among nations other than the Jews at puberty and marked the change from the infant, in the legal sense, to the full-grown man or woman. Among the Jews it is, of course, performed upon the eighth day after birth and the Biblical account of its institution makes it a distinctly dedicatory operation. Among other nations the rite was connected not only with puberty but also by an easy transition with the fertility of crops. But the folk-lore of crops, vegetation gods, fertility and generation, initiation ceremonies, and the concurrent matters of menstruation, tests of virginity, and the like is a very wide subject upon which volumes have been, and might continue to be, written. Dr. Knott's little paper is a useful collection of notes for those who may wish to pursue the subject further.

RATHER AMBIGUOUS.

THE following advertisement appearing in an excellent gazette for medical students is not happily worded.

> FOR SALE.—Ashby & Wright's Diseases of Children, in good condition; 12*s*.—Apply Editor.

THE CAUSE OF POISONING BY HAWTHORN BUDS AND CERTAIN OTHER PLANTS.

A CORRESPONDENT of the *Chemist and Druggist* of June 9th ascribes the poisonous properties of hawthorn buds to an abundance of crystals of calcium oxalate, the presence of which he has identified by a microscopical examination. The buds are commonly known in various parts of England as "bread and cheese" and are frequently eaten by children. The dangerous nature of the custom has recently been emphasised by the death of a girl at Penrith. A further examination of the leaves at a later stage showed that the crystals had disappeared. It is curious to note that in some other plants—e.g., rhubarb—the acidity of the young plants is not due to oxalic acid but probably to malic, citric, and tartaric acids; the oxalic acid appears at a later stage. That oxalic acid is the cause of poisoning by hawthorn buds receives support from the following case. A farmer in the Midlands having lost a number of cattle suspected that death was caused by plants with an unusual leaf which were growing on the grazing ground. Specimens of the plants were submitted to a botanist who recognised them as belonging to a species of *Dipsacus*. A chemical examination of the leaves revealed the presence of an abundance of oxalates. A fatal case of poisoning occurred recently at King's Heath through a child eating dandelion flower buds and a careful examination of the field revealed no trace of any plants known to contain oxalic acid. It is probable that in this case also oxalates were present in the flower buds.

HOLIDAYS FOR POOR CHILDREN.

THE Rev. J. W. Atkinson of "Claremont," Cowley-road, London, N.E., sends us an appeal on behalf of East-end slum children to whom a day in the country means so much. The East London Mission, of which our correspondent is the president, informs us that the entire cost of giving a day's holiday in the country to each poor slum child, including a substantial meal, is 1*s*. per head, and even this small sum will be thankfully received by the committee of the mission. Probably there is little to be gained from a physiological point of view by one day's outing in the country but the ray of sunshine which it brings into the sordid lives of the children of our slums has a valuable mental effect.

AUGUST BANK HOLIDAY ON THE CONTINENT.

THE Great Eastern Railway Company announces that tickets at reduced fares available for eight days will be issued to Brussels from August 1st to 4th inclusive and August 6th, and to Zürich, via Harwich and Antwerp. Dining and breakfast cars are run between London and Parkeston Quay, Harwich, on the Antwerp service, and passengers leaving London in the evening reach Brussels next morning after a comfortable night's rest on board the steamer. For visiting The Hague, Scheveningen, and Amsterdam special facilities are offered *viâ* the Company's Royal British Mail Harwich-Hook of Holland route. A corridor train with vestibuled carriages, dining and breakfast cars is to be run on the Hook of Holland service between London and Harwich. From the Hook of Holland through carriages and restaurant cars are run in the North and South German express trains to Cologne, Basle, and Berlin, reaching Cologne at noon and Basle and Berlin in the evening. For the convenience of passengers tickets dated in advance can be obtained at the Liverpool-street Station Continental Enquiry and Booking Offices. The Danish Royal Mail steamers of the Forenede line of Copenhagen will leave Harwich for Esbjerg (on the west coast of Denmark) on August 2nd and 4th, returning on August 7th and 8th. The General Steam Navigation Company's steamers will leave Harwich on August 1st and 4th for Hamburg, returning on August 5th and 8th.

◆

ERRATA.—Dr. James Fletcher, some remarks by whom are reported in THE LANCET of July 21st, p. 180, is resident medical officer of the Ham Green Fever Hospital, Bristol, and does not (as inadvertently stated in the report) represent the Metropolitan Asylums Board. —In the analysis given of "Invalid Port," on p. 1833, of THE LANCET of June 30th, the figures for alcohol when corrected for temperature should read: alcohol by weight 18·06 per cent., by volume 22·18 per cent., equal to proof spirit 38 87 per cent.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

During the week marked copies of the following newspapers have been received:—*Eastbourne Chronicle, Glasgow News, Manchester Courier, Manchester Guardian, Birmingham Post, Daily Express, Bristol Mercury, Bradford Telegraph, Dublin Independent, Leeds Post, Sheffield Independent, Daily Mail, Leicester Post, Sheffield Telegraph, Westminster Gazette, Cardiff Mail, Globe, Leeds and Yorkshire Mercury, Bradford Observer, Freeman's Journal, Devon Gazette, Darlington Echo, Northampton Reporter, Dublin Times, Hull Mail, Belfast Whig, &c.*

TUESDAY (31st).—POST GRADUATE COLLEGE (West London Hospital Hammersmith-road, W.).—10 30 A.M. Dr Moullin Gynæcological Operations. 2 P.M.: Medical and Surgical Clinics. 2.15 P.M.: Dr Ball: Diseases of the Throat, Nose, and Ear 2 30 P.M.: X Rays. Operations. Dr Abraham *Diseases of the Skin.*

WEDNESDAY (1st).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: Dr Ball Diseases of the Throat, Nose, and *Ear* *Dr Saunders*: *Diseases of Children.* 2 P.M.: Medical and Surgical Clinics. 2 30 P.M.: X Rays. Operations. CENTRAL LONDON THROAT AND EAR HOSPITAL (Gray's Inn road, W.C.).—5 P.M.: Demonstration:—Mr Stuart Low: Ear

THURSDAY (2nd).—POST GRADUATE COLLEGE (West London Hospital Hammersmith road, W.).—2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: X Rays Operations. Mr Dunn: Diseases of the Eye.

FRIDAY (3rd).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith road, W.).—10 30 A.M. Dr Moullin Gynæcological Operations. 2 P.M.: Medical and Surgical *Clinics.* 2.15 P.M.: Dr Ball: *Diseases* of the Throat, Nose, and Ear 2.30 P.M.: X Rays Operations. Dr Abraham: Diseases of the Skin

SATURDAY (4th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith road, W.).—10 A.M.: Dr Ball: Diseases of the Throat, Nose and Ear 2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: X Rays Operations.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

THE Index to Vol I. of 1906, which was completed with the issue of June 30th, and the Title-page to the Volume, were given in THE LANCET of July 7th.

VOLUMES AND CASES.

VOLUMES for the first half of the year 1906 are now ready. Bound in cloth, gilt lettered, price 18*s*, carriage extra.

Cases for binding the half-year's numbers are also ready. Cloth, gilt lettered, price 2*s*, by post 2*s*. 3*d*.

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates *additional* postage above the ordinary rate allowed for in the *terms* of subscriptions. Any demand for increased rates, on *this or on* any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

Communications, Letters, &c., have been received from—

An original and novel feature of "THE LANCET General Advertiser" is a Special Index to Advertisements on pages 2 and 4, which not only affords a ready means of finding any notice but is in itself an *additional* advertisement.

Answers are now received at this Office, by special arrangement, to advertisements appearing in THE LANCET.

The Manager cannot hold himself responsible for the return of testimonials, &c., sent to the Office in reply to Advertisements; copies only should be forwarded.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Office, 423, Strand, London, to whom all letters relating to Advertisements or Subscriptions should be addressed.

THE LANCET can be obtained at all Messrs. W. H. Smith and Son's and other Railway Bookstalls throughout the United Kingdom. Advertisements are also received by them and all other Advertising Agents.

Agent for the Advertisement Department in France—J. ASTIER, 31, Rue Bapts, Asnières, Paris.

A Clinical Lecture

ON

THE HANDS OF SURGEONS AND ASSISTANTS IN OPERATIONS.

Delivered at University College Hospital,

BY ARTHUR E. J. BARKER, F.R.C.S. ENG.,
SURGEON TO THE HOSPITAL, ETC.

GENTLEMEN,—We have now arrived at an era in which we may claim to know a good deal about septic processes. We also know something at least about the life-history of most of the organisms upon which these processes depend, thanks to the patient labours of countless bacteriologists. It is also now pretty well understood how the various septic fungi may be destroyed by heat or chemical agents. But it is only comparatively recently that the several avenues by which the dreaded microbes gain access to the living tissues have been more or less clearly recognised and their relative dangers apportioned. And only more recently still has this knowledge led to fairly practical efforts—first, towards the reduction in their numbers in all localities where operations are undertaken, and, secondly, to their exclusion from the field of operation during the procedure itself. But notwithstanding this advance much remains to be done in the direction of utilising the knowledge gained.

The avenues of infection may be thus summarised. 1. Access to injured surfaces from within the patient's own body—e.g., lungs, alimentary and genito-urinary tract. 2. Access to injured surfaces from without. Under this last heading, with which we are alone concerned to-day, the possible sources of infection of a recent wound are: (*a*) the surrounding air and solids; (*b*) the object which has made the wound; (*c*) the instruments employed in treatment; (*d*) the ligatures, swabs, and dressings employed and the clothing of operator and assistant which may come in contact with the wound; (*e*) the patient's own skin and hair; and (*f*) the surgeon's and assistants' hands.

Now *these half-dozen possible* avenues of infection are not all of the same importance. This has been proved by a long series of original bacteriological investigations of the most laborious and ingenious nature; and if I were to give you the mere titles of only those of them which I have myself carefully studied the list might be so long as to discourage some of you. But the following conclusions may be drawn from all this work—theoretical, experimental, and practical.

(*a*) First, that the air of most rooms devoted to surgical operations, if the usual precautions as to general cleanliness are adopted and if they are not too crowded and if rapid currents of air are avoided, is not such a danger to open wounds as was formerly supposed in the days of the carbolic spray. This is not to say that the influence of the air as a germ carrier can be ignored as a *quantité négligeable* in all cases and under all conditions. It means simply that with ordinary commonsense precautions as to cleanliness, especially of the floor, and stillness of the air of a room we can operate in it without undue anxiety. That the absence of common sense is conspicuous in the arrangements with regard to some operating rooms is quite another matter. Rooms are dangerous to wounds in proportion to the numbers of people in them and to the activity of the movements of these persons to and fro. In a well-known clinical lecture room the following averages were established by a long series of bacteriological observations. When occupied by the usual audience the exposure for an hour of a four-inch Petri dish with sterilised agar showed on cultivation 155 colonies of organisms. On the other hand, when the same room was empty and the air at rest a similar exposure only showed 37. In contrast to this the aseptic operation theatre of the same institution in use and at rest only showed 60 and three colonies respectively after an hour's exposure.

(*b*) As to a wound made by an instrument or other object which is dirty, it need only be said that if seen early and it is possible the area involved should be cleanly *excised* and then the resulting wound treated as aseptic. If seen too late for this it should be thoroughly scrubbed and treated with antiseptics and left open.

(*c*) Speaking generally, the instruments employed in surgical operations can nearly all be rendered sterile by careful washing and boiling in soda solution. There are, however, some which are spoiled by boiling and the common antiseptics, and among these the most important are knives, scissors, and needles. Fortunately, washing with hot water and soap, followed by immersion for a quarter of an hour in methylated spirit, is quite adequate to render their plane surfaces aseptic. It may be said, then, that infection from an instrument can easily be prevented.

(*d*) The same may be said of the overalls, swabs, dressings, and bandages employed in most cases if saturated steam be employed. The last three, as you know, are in my own technique the same thing. For the sake of simplification of procedure my swabs are merely eight-inch lengths cut off the four-fold gauze rollers also to be used as bandages and dressings and all come out of the same sterilising drum in most cases. Simplification of procedure is to my mind one of the most important desiderata in aseptic surgery and is very sadly neglected at present. It eliminates many opportunities of confusion and of accidental contamination and saves much time and thought in preparation and manipulation as well as much expense.

On the subject of ligatures and sutures much might be said. The amount of investigation as to the best material to employ and the modes of its preparation is simply enormous. But it must not be forgotten that almost any material used for ligatures may be left in any tissue of the body, if *sterile*, without hurt if in small quantity. It becomes, then, a question what ligature can be best sterilised and what material is so strong that its thread can be very fine and yet very strong, so that the smallest foreign body is left in a wound. But that some materials are not easily sterilised is clear. As for my own work, after giving an extended trial to many substances—catgut, tendon, horse-hair, silkworm gut, pure twist silk, and linen thread—I have for years exclusively used the last for ligatures and sutures.

But beyond all this there is the possibility of restricting the use of ligatures in a great many operations almost to zero by the use of hæmostatic forceps. This gets over a great difficulty. But we know that the *extent* to which forceps may supersede ligatures is not realised by many operators, especially abroad. In my own work ligatures are but rarely used. I do not think, for instance, that in the last 50 amputations of the breast ten have been employed, perhaps not five. The forceps of Péan and Spencer Wells have been all that was necessary.

(*e*) If you wish to realise the abundance and variety of the flora of the human skin you have only to repeat for yourself one of the many careful and extended observations made years ago on this point by several investigators abroad as follows. After one or more rigorous hot baths, with plenty of soap, put on a vest previously sterilised by steam. But *before doing* so stitch on various spots of its inner surface small, one centimetre, patches of some woven substance, say in the axillæ and groins, the abdomen, and the back. *When this* vest has been worn for the day separate these patches with sterile scissors and forceps and place each in a tube of sterile agar. After shaking and stirring them up in the fluid pour the latter into Petri dishes and place these in an incubator. After 48 hours an inspection of the results will convince you of the omnipresence of septic organisms even on a clean skin where it is not exposed to the air and will give you an idea of their relative abundance on the various parts of the body over which the little patches have been worn. If these results are obtained *from* a well-washed skin a surgeon may well be uneasy in the case of the average patient. And if this is true, how much more so must it be of the skin of the head, hands, and feet which are constantly *exposed*. If any further proof is necessary read the reports of some bacteriological tests of the number of organisms found in a cubic centimetre of water taken from the Seine in Paris first above and then below the laundry stations on its shores. The difference runs into millions. After this you will need no proof that the whole skin of a patient to be operated on requires the most careful cleansing *not once* but many times before an operation is undertaken. (Many other proofs might be given.) And why many times? Simply because though one washing with or without germicides may render the surface of the skin *relatively* pure it does not reach the hair, sweat, and sebaceous follicles which are constantly the hosts of countless microbes and these latter only come to the surface in the course of natural secretion. Individuals vary,

An original and novel feature of "THE LANCET General Advertiser" is a Special Index to Advertisements on pages 2 and 4, which not only affords a ready means of finding any notice but is in itself an *additional* advertisement.

Answers are now received at this Office, by special arrangement, to advertisements appearing in THE LANCET.

The Manager cannot hold himself responsible for the return of testimonials, &c., sent to the Office in reply to Advertisements; copies only should be forwarded.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Office, 423, Strand, London, to whom all letters relating to Advertisements or Subscriptions should be addressed.

THE LANCET can be obtained at all Messrs. W. H. Smith and Son's and other Railway Bookstalls throughout the United Kingdom. Advertisements are also received by them and all other Advertising Agents.

Agent for the Advertisement Department in France—J. ASTIER, 31, Rue Bauts, Asnières, Paris

A Clinical Lecture

ON

THE HANDS OF SURGEONS AND ASSISTANTS IN OPERATIONS.

Delivered at University College Hospital,

BY ARTHUR E. J. BARKER, F.R.C.S. ENG.,
SURGEON TO THE HOSPITAL, ETC.

GENTLEMEN,—We have now arrived at an era in which we may claim to know a good deal about septic processes. We also know something at least about the life-history of most of the organisms upon which these processes depend, thanks to the patient labours of countless bacteriologists. It is also now pretty well understood how the various septic fungi may be destroyed by heat or chemical agents. But it is only comparatively recently that the several avenues by which the dreaded microbes gain access to the living tissues have been more or less clearly recognised and their relative dangers apportioned. And only more recently still has this knowledge led to fairly practical efforts—first, towards the reduction in their numbers in all localities where operations are undertaken, and, secondly, to their exclusion from the field of operation during the procedure itself. But notwithstanding this advance much remains to be done in the direction of utilising the knowledge gained.

The avenues of infection may be thus summarised. 1. Access to injured surfaces from within the patient's own body—e.g., lungs, alimentary and genito-urinary tract. 2. Access to injured surfaces from without. Under this last heading, with which we are alone concerned to-day, the possible sources of infection of a recent wound are: (*a*) the surrounding air and solids; (*b*) the object which has made the wound; (*c*) the instruments employed in treatment; (*d*) the ligatures, swabs, and dressings employed and the clothing of operator and assistant which may come in contact with the wound; (*e*) the patient's own skin and hair; and (*f*) the surgeon's and assistants' hands.

Now these half-dozen possible avenues of infection are not all of the same importance. This has been proved by a long series of original bacteriological investigations of the most laborious and ingenious nature; and if I were to give you the mere titles of only those of them which I have myself carefully studied the list might be so long as to discourage some of you. But the following conclusions may be drawn from all this work—theoretical, experimental, and practical.

(*a*) First, that the air of most rooms devoted to surgical operations, if the usual precautions as to general cleanliness are adopted and if they are not too crowded and if rapid currents of air are avoided, is not such a danger to open wounds as was formerly supposed in the days of the carbolic spray. This is not to say that the influence of the air as a germ carrier can be ignored as a *quantité négligeable* in all cases and under all conditions. It means simply that with ordinary commonsense precautions as to cleanliness, especially of the floor, and stillness of the air of a room we can operate in it without undue anxiety. That the absence of common sense is conspicuous in the arrangements with regard to some operating rooms is quite another matter. Rooms are dangerous to wounds in proportion to the numbers of people in them and to the activity of the movements of these persons to and fro. In a well-known clinical lecture room the following averages were established by a long series of bacteriological observations. When occupied by the usual audience the exposure for an hour of a four-inch Petri dish with sterilised agar showed on cultivation 155 colonies of organisms On the other hand, when the same room was empty and the air at rest a similar exposure only showed 37. In contrast to this the aseptic operation theatre of the same institution in use and at rest only showed 60 and three colonies respectively after an hour's exposure.

(*b*) As to a wound made by an instrument or other object which is dirty, it need only be said that if seen early and it is possible the area involved should be cleanly *excised* and then the resulting wound treated as aseptic. If seen too late for this it should be thoroughly scrubbed and treated with antiseptics and left open.

(*c*) Speaking generally, the instruments employed in surgical operations can nearly all be rendered sterile by careful washing and boiling in soda solution. There are, however, some which are spoiled by boiling and the common antiseptics, and among these the most important are knives, scissors, and needles. Fortunately, washing with hot water and soap, followed by immersion for a quarter of an hour in methylated spirit, is quite adequate to render their plane surfaces aseptic. It may be said, then, that infection from an instrument can easily be prevented.

(*d*) The same may be said of the overalls, swabs, dressings, and bandages employed in most cases if saturated steam be employed. The last three, as you know, are in my own technique the same thing. For the sake of simplification of procedure my swabs are merely eight-inch lengths cut off the four-fold gauze rollers also to be used as bandages and dressings and all come out of the same sterilising drum in most cases. Simplification of procedure is to my mind one of the most important desiderata in aseptic surgery and is very sadly neglected at present. It eliminates many opportunities of confusion and of accidental contamination and saves much time and thought in preparation and manipulation as well as much expense.

On the subject of ligatures and sutures much might be said. The amount of investigation as to the best material to employ and the modes of its preparation is simply enormous. But it must not be forgotten that almost any material used for ligatures may be left in any tissue of the body, if *sterile*, without hurt if in small quantity. It becomes, then, a question what ligature can be best sterilised and what material is so strong that its thread can be very fine and yet very strong, so that the smallest foreign body is left in a wound. But that some materials are not easily sterilised is clear. As for my own work, after giving an extended trial to many substances—catgut, tendon, horse-hair, silkworm gut, pure twist silk, and linen thread—I have for years exclusively used the last for ligatures and sutures.

But beyond all this there is the possibility of restricting the use of ligatures in a great many operations almost to zero by the use of hæmostatic forceps. This gets over a great difficulty. But we know that the extent to which forceps may supersede ligatures is not realised by many operators, especially abroad In my own work ligatures are but rarely used. I do not think, for instance, that in the last 50 amputations of the breast ten have been employed, perhaps not five. The forceps of Péan and Spencer Wells have been all that was necessary.

(*e*) If you wish to realise the abundance and variety of the flora of the human skin you have only to repeat for yourself one of the many careful and extended observations made years ago on this point by several investigators abroad as follows. After one or more rigorous hot baths, with plenty of soap, put on a vest previously sterilised by steam. But before doing so stitch on various spots of its inner surface small, one centimetre, patches of some woven substance, say in the axillæ and groins, the abdomen, and the back. When this vest has been worn for the day separate these patches with sterile scissors and forceps and place each in a tube of sterile agar. After shaking and stirring them up in the fluid pour the latter into Petri dishes and place these in an incubator. After 48 hours an inspection of the results will convince you of the omnipresence of septic organisms even on a clean skin where it is not exposed to the air and will give you an idea of their relative abundance on the various parts of the body over which the little patches have been worn. If these results are obtained from a well-washed skin a surgeon may well be uneasy in the case of the average patient. And if this is true, how much more so must it be of the skin of the head, hands, and feet which are constantly exposed. If any further proof is necessary read the reports of some bacteriological tests of the number of organisms found in a cubic centimetre of water taken from the Seine in Paris first above and then below the laundry stations on its shores. The difference runs into millions. After this you will need no proof that the whole skin of a patient to be operated on requires the most careful cleansing not once but many times before an operation is undertaken. (Many other proofs might be given) And why many times? Simply because though one washing with or without germicides may render the surface of the skin *relatively* pure it does not reach the hair, sweat, and sebaceous follicles which are constantly the hosts of countless microbes and these latter only come to the surface in the course of natural secretion. Individuals vary.

of course, as to the crops of micro-organisms they grow in their skin as well as on it and in certain callings we may expect more than others. But for surgical purposes we must assume that *every* skin claims the very closest attention before operation, no matter what class of the community the patient belongs to. And also we must remember that different parts of the body surface vary as to the abundance of their septic flora. This is seen in the experiment alluded to above.

As a general statement, wherever follicles abound in the skin, whether hair, sebaceous, or sweat, there the usual micro-organisms abound and are particularly hard to dislodge. For this reason my own reliance for the cleansing of the skin is placed in the first place upon *repeated* hot baths of the whole body wherever permissible, accompanied by vigorous scrubbing with soft soap and brush. After each bath the area to be uncovered during operation is wrapped up in some sterilised fabric after a couple of hours of soaking in 1 in 30 carbolic lotion. The increased activity of the glands of the skin induced by the baths and wraps brings the secretions to the surface and with them the parasitic organisms. The carbolic solution tends to destroy these and produces besides a certain amount of exfoliation of the superficial epidermic scales which are, as a rule, more or less infected. When this process has been repeated, if possible for some days, the skin is relatively clean. It is finally washed carefully over before operation with spirit. In those cases in which an operation has to be done soon after the patient is first seen the skin is washed with turpentine or ether thoroughly, then soaped, shaved, and scoured over and over again with hard brush and hot water and soft soap, and wrapped in the carbolic towel if possible for two hours before operation, or as near that as time permits. But in both cases, regarding the skin as still possibly impure, I have for many years adopted the practice of covering the whole of the patient's body just before operation with a sterilised sheet of double gauze or cloth through which a hole is cut only large enough to permit of the operation being done through it, while the hands of the operator and assistants are by it prevented from coming in contact with the patient's skin during the operation. This gauze extends from the patient's face to the feet and covers all his clothing and the operating table. It is cut from one of our rollers. In former days we were taught to protect the patient from the chilling effects of the spray by the use of mackintoshes, and to protect both the surgeon's hands, and therefore the patient, from the mackintoshes by covering the latter with towels wet in carbolic solution. The sprays having now gone the sooner the mackintoshes and wet towels go the better, as they cost much labour and time to clean. I have not used these for many years.

(*f*) We now come to the subject which I wish to emphasise particularly to-day—viz., the surgeon's and assistants' hands. And if this is treated somewhat in detail it is because it is admittedly one of the weakest points in our aseptic procedure and everything is not commonly done to minimise risk from the hands that might easily be done as a routine.

The question of the cleansing of the hands in the first instance is of course the most important of all. It is not too much to say that this fact is now fully established and that an enormous amount of laborious bacteriological work has been done to find out the best methods. And the number of valuable essays which have been written on the subject is very large. Having read all the most important and tried many methods I may say that I have more confidence in the results of Ahlfeld's and Fürbringer's experiments (now many years old) of sterilising the hands with very hot *running* water and pure soap and brush, followed by spirit, than in any others. This has to be employed in no perfunctory manner but over and over again for many minutes at a time. The evidence is strong that by this method of disinfection the percentage of organisms clinging to the hands is as small as, or smaller than, by any other known procedure. Nevertheless, we will do well to admit at once that after any method of cleansing a perfectly sterile hand is an exception. Moreover, it must be remembered that it has been proved over and over again bacteriologically that the surface of a hand cleansed to apparent sterility becomes after a short time re-infected from its own skin follicles in the process of sweating, &c., even if no organisms reach it from without. This all suggests several alternatives. First, that the hands should be washed frequently during all operations of any duration and this should be considered indispensable. Their own impurities which transude to the surface and others accidentally reaching them from the air or casual contact with the patient's skin, even in the case of a surgical incision into healthy tissues, are thus removed by washing over and over again during the operation.

The second alternative is the wearing of impermeable rubber gloves which can be easily sterilised and will retain within them any impurities exuding from the hands until the end of the operation. Having been one of the first to introduce rubber gloves from abroad and for a long time to use them in operating I am not speaking without experience when I say that I distrust them during operation except in very exceptional cases and value them when it is a question of keeping the hands clean *for* operation. The distrust arises from the recognised fact that they are very easily pricked, cut, or torn without the fact being recognised, and if so the fluid derived from the perspiration of the hand, which has been proved to contain numerous bacteria, escapes into the wound more or less concentrated. They are of value, however, when it is a question of dealing with foul parts before operating on clean tissues. They can be used to protect the hands from septic material and then removed. It is for this reason that they are dispensed with in most of my own operations unless I or my assistant happens to have an abrasion on the hand which is not quite healthy. Otherwise they are only used to keep the hands clean for future use. This is the reason why my house surgeons have been directed for years past to wear rubber gloves in the wards and casualty department when manipulating dirty cases. By this rule I believe we secure a higher standard of purity in our hands when it is necessary to employ them to take part in serious operations. That is to say, they are not being constantly re-infected with septic organisms. But there is a further rule which I have carried through for many years as rigidly as possible for myself, my house surgeons, and dressers and which contributes perhaps as much as anything to surgically clean hands. By this rule I train myself and my subordinates so far as possible never to touch a foul dressing with the naked hand. To avoid this there is always a trayful of sterilised forceps and other instruments at hand for every dressing and thus we save the fingers from contamination with pus and other secretions. This, of course, does not obviate the necessity of careful washing of the hands after each dressing, but under this system *there is much less* dangerous material to be washed away. And remember that a hand once fairly infected with bacteria is extremely difficult to disinfect again, even with numerous washings and germicides. If any of you doubt this statement read the experimental work of Heile on this point. This routine is really far less cumbrous than it sounds and with the loyal coöperation of house surgeons, sisters, and dressers runs smoothly enough as far as we are concerned.

Then there is a third alternative—namely, that the hands should come as little as possible in contact with fresh cut surfaces. This is a point which has for a long time appeared to me to receive far less consideration than it deserves. If it be conceded generally, as is the case, that under any or all the methods devised for cleansing the hands a certain suspicion must always remain as to their sterility it ought to follow that manipulation of fresh-cut surfaces with the naked hand should be avoided wherever possible. And certainly the extent to which it can be dispensed with is not generally realised. With a little practice the routine of employment of instruments in place of fingers during an operation can be established and in the end becomes a habit. Very extensive operations lasting a considerable time may be done from beginning to the end without the living tissues being touched by anything but sterile gauze or steel instruments. And in cases of foul wounds the advantage of keeping the hands from contact with infective materials is obvious. To do without using the tactile impressions of the fingers is not always possible in the middle of an operation but their use can, and ought to be, limited for cut surfaces. And even when we must palpate or grasp the deeper part of a wound or abdominal contents we can often do it through a double layer of gauze and so prevent immediate contact with the finger. Within the abdomen this is not always possible, but even here contact with the hands can be guarded against to a much larger extent than is commonly supposed. The old tradition that tissues ought not to be held in forceps for fear of injury to their vitality ought to be exploded.

all know now that clamps may be left, for instance, he intestine or stomach for half an hour at a time out any risk, unless badly constructed.

it one can best illustrate the procedure by taking a 'ular case. Let it be that of an extensive excision of reast. I will briefly describe to you the technique I have employed for many years past in removing this . It is quite possible that the objects of several of the s have been misinterpreted by some bystanders seeing for the first time. Of course, the first aim nowadays noving a cancerous breast is to take it away completely vith it all the various structures about it in which the hatic tracts lie. On this subject in its various bearings we confer in the wards and trace the course of the various hatic channels leading from the organ. Next in im- ance to this is the planning our technique so that even in nost wide-reaching operations the asepsis is so complete primary union is the result. In the first place, , the patient has several hot baths with soft soap plenty of scrubbing. Then the axilla is shaved and the al mentioned above is continued until the operation. But iew of the fact that the skin may not yet be blameless that the hands of assistants and surgeon may come in tact with it inadvertently, I have for years been in the it of throwing over the patient and operating table a ile sheet in which a hole is cut just large enough for the ration. Such a sheet lies closer to the patient's skin and less easily disturbed than a number of towels pinned ether. Except over the area of operation neither the ient's skin, clothes, or the table can be touched, and as sheet is sterile no harm comes from contact with hand, ab, or instruments.

To be steadied for the first incision the slippery breast is isped by the fingers with a swab of gauze interposed. d for the wide dissection of the skin away from the ammary fat before the latter with the breast is dissected the thoracic wall, the skin is best held by the operator in r usual gauze swabs and retracted by the assistant with oks wherever necessary. In no case is it necessary for the nds to touch the raw surfaces. And further on when the east and fat are being separated with or without the ctoral muscle from the thoracic wall it is easier to hold if rapped in a large sheet of gauze which saves the hands from ming in contact with the part of its skin which is being moved and prevents also the latter from touching the raw rface. Finally, as the breast and its peri-mammary fat ang free except for their attachments towards the axilla the st of the clearing round the vessels and nerves can be done y blunt dissection with the closed ends of a broad-bladed urved scissors aided here and there by a snip with the same hile the left hand grasps the breast enveloped in gauze.

But all the time this large wound if left open to the air would be liable to be contaminated by dust or the breath of those closely occupied around it. This is guarded against n this way. As fast as the surgeon makes the wound and the bleeding vessels are clamped the assistant is told to cover it up with gauze and to press upon the latter firmly. This has the double effect of stopping oozing and protecting the surface from infection. For the breath of the surgeon and assistants is certainly a danger. We know that the mouth of even cleanly persons is the seat of an abundant flora. And that these escape in the breath has been proved conclusively.

When the removal of the whole mass has been completed by the final clearance of the axilla to its highest boundary, the gauze is removed and a rapid survey of the whole wound takes place, forceps being removed or fresh bleeding points being clamped if necessary. Then the dried wound is filled again with gauze, one continuous piece from a six-yard roll being used by choice to avoid the risk of any disconnected pieces being overlooked. Then while the assistant presses the flaps together over the gauze the stitches are introduced from one end of the wound to the other. When all are in place the long strip of gauze is drawn out by degrees, bringing away any traces of blood or clot, and while the assistant presses the flaps firmly down upon the thoracic wall the stitches are knotted, the ends are cut, and an aseptic gauze and cellulose packing is firmly bandaged over the whole area of operation without drainage.

This operation is merely taken as an illustration of a lengthy procedure which can be carried out from the beginning to the end without the fingers or anything which touches them being brought in contact with fresh-cut surfaces. This appears to me a most important matter so long as we are obliged to admit that the hand is almost impossible to sterilise and to keep sterile. But while we are able to sterilise knife, forceps, retractors, and scissors and to cover the wound as it is made with sterile gauze we can eliminate the chief risks of infection even of the most extensive wounds.

But there is another point. You notice that only one assistant is allowed to have any part in the operation. This is only to be consistent. For if two hands are to some extent a risk any greater number increase that risk And it is easier for an operator to control the doings of one assistant during an operation than those of several. Moreover, that one assistant knowing that at any moment he may be called upon to help in the most complicated procedure day or night will endeavour day and night to keep his hands out of foul matters or wear gloves where he has perforce to deal with them. Again, he is enjoined to do as I have done myself, for years, before operating—namely, to wash his mouth carefully with an antiseptic, having seen to it that he has no carious teeth, no influenza cold, or other source of sepsis in his air passages. If either of those immediately concerned in an operation have any of these the mouth and nose are covered with a fourfold sterile gauze bandage tied behind the head. I began this form of "muzzle" in exceptional cases eight or ten years ago and now adopt it almost as a matter of routine except in trifling cases.

To illustrate the desirability of this measure I should like to relate to you briefly an experiment of the late Professor Mikulicz, which may not be familiar to some of you and the results of which I saw eight years ago. Being anxious to study the possibility of infection from the surgeon's breath while operating he proceeded as follows. Starting with the ascertained fact that no mouth is free of suspicion as to being septic but that the organisms commonly present in it are not easy to recognise in a moment in a culture and that the air of a room contains many common forms, he conceived the idea of inoculating the mouth with a potent pure culture of a bacillus easily cultivated and easily recognised and which was still so uncommon in rooms set apart for operation that it might be assumed that they would not be present accidentally in the air of the same. One of his assistants having therefore washed his mouth freely with a sterile salt solution in which an abundant culture of the bacillus prodigiosus (producing, as you know, a blood-red pigment) was mixed spoke for ten minutes quietly over four Petri dishes of sterilised agar-agar placed on a table at the same distance from the mouth as an operation wound would be. These dishes were then covered and placed in an incubator. The mouth in these experiments was in the first instance uncovered. The result was remarkable. After incubation the aggregate of colonies of bacillus prodigiosus, with its characteristic colour, on the four dishes was in one experiment 119, in a similar one 119, and in a third 581. The mouth and nose of the experimenter were then covered with a *single* layer of sterile gauze and he spoke over four fresh dishes under similar conditions. After incubation three colonies of bacillus prodigiosus were found on one set and 17 on another. The experimenter then covered his nose and mouth with a *double* layer of sterile gauze and repeated the operation over four fresh dishes for ten minutes, the result being that one set of dishes was found sterile after incubation and another set had only one colony. Control dishes open at the same time showed countless colonies. These experiments were repeated over

Abbreviated Table giving the Results of Experiments in the late Professor Mikulicz's Klinic in Breslau. (1898.)

Ten minutes' exposure of plate while quietly talking.	Badly applied.	Well applied.	Well applied.	Well applied.	Well applied.	Well applied.	Three or four coughs during the ten minutes' exposure.		Operator sneezed once during the ten minutes' exposure.	
Without gauze ...	119	119	581	362	579	233	265	223	Countless.	Countless.

of course, as to the crops of micro-organisms they grow in their skin as well as on it and in certain callings we may expect more than others. But for surgical purposes we must assume that *every* skin claims the very closest attention before operation, no matter what class of the community the patient belongs to. And also we must remember that different parts of the body surface vary as to the abundance of their septic flora. This is seen in the experiment alluded to above.

As a general statement, wherever follicles abound in the skin, whether hair, sebaceous, or sweat, there the usual micro-organisms abound and are particularly hard to dislodge. For this reason my own reliance for the cleansing of the skin is placed in the first place upon *repeated* hot baths of the whole body wherever permissible, accompanied by vigorous scrubbing with soft soap and brush. After each bath the area to be uncovered during operation is wrapped up in some sterilised fabric after a couple of hours of soaking in 1 in 30 carbolic lotion. The increased activity of the glands of the skin induced by the baths and wraps brings the secretions to the surface and with them the parasitic organisms. The carbolic solution tends to destroy these and produces besides a certain amount of exfoliation of the superficial epidermic scales which are, as a rule, more or less infected. When this process has been repeated, if possible for some days, the skin is relatively clean. It is finally washed carefully over before operation with spirit. In those cases in which an operation has to be done soon after the patient is first seen the skin is washed with turpentine or ether thoroughly, then soaped, shaved, and scoured over and over again with hard brush and hot water and soft soap, and wrapped in the carbolic towel if possible for two hours before operation, or as near that as time permits. But in both cases, regarding the skin as still possibly impure, I have for many years adopted the practice of covering the whole of the patient's body just before operation with a sterilised sheet of double gauze or cloth through which a hole is cut only large enough to permit of the operation being done through it, while the hands of the operator and assistants are by it prevented from coming in contact with the patient's skin during the operation. This gauze extends from the patient's face to the feet and covers all his clothing and the operating table. It is cut from one of our rollers. In former days we were taught to protect the patient from the chilling effects of the spray by the use of mackintoshes, and to protect both the surgeon's hands, and therefore the patient, from the mackintoshes by covering the latter with towels wet in carbolic solution. The sprays having now gone the sooner the mackintoshes and wet towels go the better, as they cost much labour and time to clean. I have not used these for many years.

(*f*) We now come to the subject which I wish to emphasise particularly to-day—*viz.*, the surgeon's and assistants' hands. And if this is treated somewhat in detail it is because it is admittedly one of the weakest points in our aseptic procedure and everything is not commonly done to minimise risk from the hands that might easily be done as a routine.

The question of the cleansing of the hands in the first instance is of course the most important of all. It is not too much to say that this fact is now fully established and that an enormous amount of laborious bacteriological work has been done to find out the best methods. And the number of valuable essays which have been written on the subject is very large. Having read all the most important and tried many methods I may say that I have more confidence in the results of Ahlfeld's and Fürbringer's experiments (now many years old) of sterilising the hands with very hot *running* water and pure soap and brush, followed by spirit, than in any others. This has to be employed in no perfunctory manner but over and over again for many minutes at a time. The evidence is strong that by this method of disinfection the percentage of organisms clinging to the hands is as small as, or smaller than, by any other known procedure. Nevertheless, we will do well to admit at once that after any method of cleansing a perfectly sterile hand is an exception. Moreover, it must be remembered that it has been proved over and over again bacteriologically that the surface of a hand cleansed to apparent sterility becomes after a short time re-infected from its own skin follicles in the process of sweating, &c., even if no organisms reach it from without. This all suggests several alternatives. First, that the hands should be washed frequently during all operations of any duration and this should be considered indispensable. Their own impurities which transude to the surface and others accidentally reaching them from the air or casual contact with the patient's skin, even in the case of a surgical incision into healthy tissues, are thus removed by washing over and over again during the operation.

The second alternative is the wearing of impermeable rubber gloves which can be easily sterilised and will retain within them any impurities exuding from the hands until the end of the operation. Having been one of the first to introduce rubber gloves from abroad and for a long time to use them in operating I am not speaking without experience when I say that I distrust them during operation except in very exceptional cases and value them when it is a question of keeping the hands clean *for* operation. The distrust arises from the recognised fact that they are very easily pricked, cut, or torn without the fact being recognised, and if so the fluid derived from the perspiration of the hand, which has been proved to contain numerous bacteria, escapes into the wound more or less concentrated. They are of value, however, when it is a question of dealing with foul parts before operating on clean tissues. They can be used to protect the hands from septic material and then removed. It is for this reason that they are dispensed with in most of my own operations unless I or my assistant happens to have an abrasion on the hand which is not quite healthy. Otherwise they are only used to keep the hands clean for future use. This is the reason why my house surgeons have been directed for years past to wear rubber gloves in the wards and casualty department when manipulating dirty cases. By this rule I believe we secure a higher standard of purity in our hands when it is necessary to employ them to take part in serious operations. That is to say, they are not being constantly re-infected with septic organisms. But there is a further rule which I have carried through for many years as rigidly as possible for myself, my house surgeons and dressers and which contributes perhaps as much as anything to surgically clean hands. By this rule I train myself and my subordinates so far as possible never to touch a foul dressing with the naked hand. To avoid this there is always a trayful of sterilised forceps and other instruments at hand for every dressing and thus we save the fingers from contamination with pus and other secretions. This, of course, does not obviate the necessity of careful washing of the hands after each dressing but under this system *there is much less* dangerous material to be washed away. And remember that a hand once fairly infected with bacteria is extremely difficult to disinfect again, even with numerous washings and germicides. If any of you doubt this statement read the experimental work of Heile on this point. This routine is really far less cumbrous than it sounds and with the loyal coöperation of house surgeons, sisters, and dressers runs smoothly enough as far as we are concerned.

Then there is a third alternative—namely, that the hands should come as little as possible in contact with fresh cut surfaces. This is a point which has for a long time appeared to me to receive far less consideration than it deserves. If it be conceded generally, as is the case, that under any or all the methods devised for cleansing the hands a certain suspicion must always remain as to their sterility it ought to follow that manipulation of fresh-cut surfaces with the naked hand should be avoided wherever possible. And certainly the extent to which it can be dispensed with is not generally realised. With a little practice the routine of employment of instruments in place of fingers during an operation can be established and in the end becomes a habit. Very extensive operations lasting a considerable time may be done from beginning to the end without the living tissues being touched by anything but sterile gauze or steel instruments. And in cases of foul wounds the advantage of keeping the hands from contact with infective materials is obvious. To do without using the tactile impressions of the fingers is not always possible in the middle of an operation but their use can, and ought to be, limited for cut surfaces. And even when we must palpate or grasp the deeper part of a wound or abdominal contents we can often do it through a double layer of gauze and so prevent immediate contact with the finger. Within the abdomen this is not always possible, but even here contact with the hands can be guarded against to a much larger extent than is commonly supposed. The old tradition that tissues ought not to be held in forceps for fear of injury to their vitality ought to be exploded.

We all know now that clamps may be left, for instance, on the intestine or stomach for half an hour at a time without any risk, unless badly constructed.

But one can best illustrate the procedure by taking a particular case. Let it be that of an extensive excision of the breast. I will briefly describe to you the technique which I have employed for many years past in removing this organ. It is quite possible that the objects of several of the details have been misinterpreted by some bystanders seeing them for the first time. Of course, the first aim nowadays in removing a cancerous breast is to take it away completely and with it all the various structures about it in which the lymphatic tracts lie. On this subject in its various bearings we often confer in the wards and trace the course of the various lymphatic channels leading from the organ. Next in importance to this is the planning our technique so that even in the most wide-reaching operations the asepsis is so complete that primary union is the result. In the first place, then, the patient has several hot baths with soft soap and plenty of scrubbing. Then the axilla is shaved and the ritual mentioned above is continued until the operation. But in view of the fact that the skin may not yet be blameless and that the hands of assistants and surgeon may come in contact with it inadvertently, I have for years been in the habit of throwing over the patient and operating table a sterile sheet in which a hole is cut just large enough for the operation. Such a sheet lies closer to the patient's skin and is less easily disturbed than a number of towels pinned together. Except over the area of operation neither the patient's skin, clothes, or the table can be touched, and as the sheet is sterile no harm comes from contact with hand, swab, or instruments.

To be steadied for the first incision the slippery breast is grasped by the fingers with a swab of gauze interposed. And for the wide dissection of the skin away from the mammary fat before the latter with the breast is dissected off the thoracic wall, the skin is best held by the operator in our usual gauze swabs and retracted by the assistant with hooks wherever necessary. In no case is it necessary for the hands to touch the raw surfaces. And further on when the breast and fat are being separated with or without the pectoral muscle from the thoracic wall it is easier to hold if wrapped in a large sheet of gauze which saves the hands from coming in contact with the part of its skin which is being removed and prevents also the latter from touching the raw surface. Finally, as the breast and its peri-mammary fat hang free except for their attachments towards the axilla the rest of the clearing round the vessels and nerves can be done by blunt dissection with the closed ends of a broad-bladed curved scissors aided here and there by a snip with the same while the left hand grasps the breast enveloped in gauze.

But all the time this large wound if left open to the air would be liable to be contaminated by dust or the breath of those closely occupied around it. This is guarded against in this way. As fast as the surgeon makes the wound and the bleeding vessels are clamped the assistant is *told to cover* it up with gauze and to press upon the latter firmly. This has the double effect of stopping oozing and protecting the surface from infection. For the breath of the surgeon and assistants is certainly a danger We know that the mouth of even cleanly persons is the seat of an abundant flora. And that these escape in the breath has been proved conclusively.

When the removal of the whole mass has been completed by the final clearance of the axilla to its highest boundary, the gauze is removed and a rapid survey of the whole wound takes place, forceps being removed or fresh bleeding points being clamped if necessary. Then the dried wound is filled again with gauze, one continuous piece from a six-yard roll being used by choice to avoid the risk of any disconnected pieces being overlooked. Then while the assistant presses the flaps together over the gauze the stitches are introduced from one end of the wound to the other. When all are in place the long strip of gauze is drawn out by degrees, bringing away any traces of blood or clot, and while the assistant presses the flaps firmly down upon the thoracic wall the stitches are knotted, the ends are cut, and an aseptic gauze and cellulose packing is firmly bandaged over the whole area of operation without drainage.

This operation is merely taken as an illustration of a lengthy procedure which can be carried out from the beginning to the end without the fingers or anything which touches them being brought in contact with fresh-cut surfaces. This appears to me a most important matter so long as we are obliged to admit that the hand is almost impossible to sterilise and to keep sterile. But while we are able to sterilise knife, forceps, retractors, and scissors and to cover the wound as it is made with sterile gauze we can eliminate the chief risks of infection even of the most extensive wounds.

But there is another point. You notice that only one assistant is allowed to have any part in the operation. This is only to be consistent. For if two hands are to some extent a risk any greater number increase that risk And it is easier for an operator to control the doings of one assistant during an operation than those of several Moreover, that one assistant knowing that at any moment he may be called upon to help in the most complicated procedure day or night will endeavour day and night to keep his hands out of foul matters or wear gloves where he has perforce to deal with them. Again, he is enjoined to do as I have done myself, for years, before operating—namely, to wash his mouth carefully with an antiseptic, having seen to it that he has no carious teeth, no influenza cold, or other source of sepsis in his air passages. If either of those immediately concerned in an operation have any of these the mouth and nose are covered with a fourfold sterile gauze bandage tied behind the head. I began this form of "muzzle" in exceptional cases eight or ten years ago and now adopt it almost as a matter of routine except in trifling cases.

To illustrate the desirability of this measure I should like to relate to you briefly an experiment of the late Professor Mikulicz, which may not be familiar to some of you and the results of which I saw eight years ago. Being anxious to study the possibility of infection from the surgeon's breath while operating he proceeded as follows. Starting with the ascertained fact that no mouth is free of suspicion as to being septic but that the organisms commonly present in it are not easy to recognise in a moment in a culture and that the air of a room contains many common forms, he conceived the idea of inoculating the mouth with a potent pure culture of a bacillus easily cultivated and easily recognised and which was still so uncommon in rooms set apart for operation that it might be assumed that they would not be present accidentally in the air of the same. One of his assistants having therefore washed his mouth freely with a sterile salt solution in which an abundant culture of the bacillus prodigiosus (producing, as you know, a blood-red pigment) was mixed spoke for ten minutes quietly over four Petri dishes of sterilised agar-agar placed on a table at the same distance from the mouth as an operation wound would be. These dishes were then covered and placed in an incubator. The mouth in these experiments was in the first instance uncovered. The result was remarkable. After incubation the aggregate of colonies of bacillus prodigiosus, with its characteristic colour, on the four dishes was in one experiment 119, in a similar one 119, and in a third 581. The mouth and nose of the experimenter were then covered with a *single* layer of sterile gauze and he spoke over four fresh dishes under similar conditions. After incubation three colonies of bacillus prodigiosus were found on one set and 17 on another. The experimenter then covered his nose and mouth with a *double* layer of sterile gauze and repeated the operation over four fresh dishes for ten minutes, the result being that one set of dishes was found sterile after incubation and another set had only one colony. Control dishes open at the same time showed countless colonies. These experiments were repeated over

Abbreviated Table giving the Results of Experiments in the late Professor Mikulicz's Klinik in Breslau. (1898.)

Ten minutes' exposure of plate while quietly talking.	Badly applied.	Well applied.	Well applied.	Well applied.	Well applied.	Well applied.	Three or four coughs during the ten minutes' exposure.		Operator sneezed once during the ten minutes' exposure.	
Without gauze ...	119	119	581	352	679	233	255	223	Countless.	Countless.
With single layer of gauze	27	3	17	20	42	10	180	0	—	—
With double layer of gauze	24	0	1	0	0	1	0	0	505	325
	Total of colonies on four agar plates.									

and over again and gave in all cases practically the same results. But there was a remarkable exception. In one experiment with a double layer of gauze over the nose and mouth the operator sneezed and 506 and 325 colonies were found where the dishes had been practically sterile before. Having seen the result of these cultivations myself and examined the dishes I confess I was impressed with the number of organisms which could be breathed out of the mouth in talking and the simplicity of the means of arresting them which I have since practised.

Now if these easily recognisable bacilli can be distributed thus it is fair to assume that those numerous pathogenic organisms which we know flourish in almost every mouth can also be sown broadcast in the same way. The moral to be drawn from all this is: first, that operators and assistants should look to the cleanness of their mouths; secondly, that as little talking as possible should be indulged in in the neighbourhood of an open wound; and thirdly, that at least where there is a suspicion of an unusual infectivity of the operator's mouth or air passages, if not in every trifling operation, these should always be covered with some porous protector.

But when all is said and done the fact remains that when wounds are infected from without it is a question in most cases of a direct contagion with hands, instruments, or other bodies applied to it rather than through matters carried through the air. It is for this reason that stress has been laid upon the urgent need of using sterilisable instruments instead of the hands wherever possible. That this can be done has been proved in much of my own work and I should like to see the practice extended. To work aseptically means to a large extent a constant and serious consideration day and night how we may best prevent ourselves from becoming the carriers of infection. And if we are successful in this our paraphernalia and ritual become simple and the simpler the better, a chain being only as strong as its weakest link. If these remarks were not addressed to my own class who are constantly present in the operating theatres and wards it might be necessary to go more into detail. The aim here has been rather to point out the principles which underlie details with which you ought to be familiar.

INTERNAL SECRETION AND THE DUCTLESS GLANDS.[1]

BY SWALE VINCENT, M.B. LOND., D.SC. EDIN.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF MANITOBA,
WINNIPEG, CANADA.

PART I.—INTRODUCTORY.

Secretion and internal secretion.—By the term "secretion," applied in its most general sense, is understood the separation out of materials from the animal body. This, the original conception of the process, has been long extended to include also the preliminary preparation or more or less complete elaboration of the materials which are supplied by the blood circulating through the organ. Johannes Müller[2] pointed out that the whole process of secretion consists of two phases, the production of certain materials, and the casting out of these materials upon a surface either in the interior or upon the exterior of the body. The first phase he called "secretion," the second "excretion." In some cases the material eliminated might be found in the blood stream and was simply separated by the tissues of the organ and passed out. This applied to the urea of the urine, which was looked upon by Müller as a pure case of "excretion." The distinction thus set up has, however, not been retained in a very strict manner. The term "excretion" is mostly applied at the present time in rather a vague kind of way to denote the process of elimination of waste products from the body. The idea of secretion has from the earliest period of physiology been associated with what are called "glandular" organs. There is no need in this place to *describe a "gland" in any detail.* Its essential is a surface provided with epithelial cells, usually of a columnar or cubical shape, and characterised by the presence of tiny granules of the substance to be secreted or its precursor. This surface may be a simple pouch or may be very complicated by the extension of the involuted portion and by the growth of side branches, as in the case of the compound racemose glands. In these glands the terminal portion of the tubes or "alveoli" are the secreting portions, while the tubes leading to the exterior are the "ducts."

The term gland was applied in the earlier days of anatomy *to a very varied group of structures* which resembled each other in certain general external characters.[3] Then it was discovered that some of these organs possessed a "duct" by means of which a "secretion" was poured out. Such a structure was, and is still, regarded as the most typical form of "gland." But others of these glands possessed no duct and were therefore called "ductless glands," or in Germany more usually "Blutgefüssdrüsen." The hypothesis soon arose that in these cases the specific secretion is passed into the blood stream and the process is termed "internal secretion." The term "internal secretion" was, however, so far as I can ascertain, first used by Claude Bernard[4] who described the glycogenic function of the liver as the "sécrétion interne," while he referred to the preparation of the bile as the "sécrétion externe,"[5] and was subsequently *extended by Brown-Séquard and by Schiff to apply* to the process of secretion in the "ductless glands." In some cases the material secreted by the ductless glands is passed, not directly into the blood stream, but indirectly by way of the lymphatic vessels. This applies to the specific secretion of the thyroid gland.

The "ductless glands," according to the original conception, were the thyroids, the pituitary body, the suprarenal capsules, the spleen, the thymus gland, and the lymphatic glands. But soon it was discovered that some of these had not a glandular structure—i.e., they did not consist of epithelial "secreting" cells; some, for example, such as the spleen and the lymphatic glands, belonged to another category of organs.[6] On the other hand, some new organs, such as the carotid and coccygeal bodies and the parathyroids, have been *added to the list.* The thymus occupies a quite anomalous position. It is in its earlier stages an "epithelial" organ, and possibly has a secretory function, but later in the course of its development it becomes for the most part a mass of adenoid tissue. The structures usually included at the present time under the title of "ductless glands" are the thyroid gland, the parathyroid glands, the cortical suprarenal gland, the medullary suprarenal gland, the pituitary body, the carotid and coccygeal bodies, and possibly the thymus. Some authors would reduce this list by cutting out the medulla of the suprarenal capsule and the carotid gland on the ground that they consist not of epithelial secreting cells but of a special type of tissue—the chromaffin tissue.[7] It is believed that these "ductless glands" manufacture and pour, directly or indirectly, into the blood stream some substance or substances which are of service to the economy, either by supplying a need or by destroying other substances which are needless or positively harmful. This last function, that of tgiftung," is usually ascribed to the thyroid and para- oid, and there is some little evidence that the same tion may be performed by the cortical suprarenal gland. nothing has been said so far to preclude our attributing uscles, nerves, and indeed every tissue in the body an nally secreting function. It is obvious that in the dest sense of the expression all tissues and organs of body may be said to have an internal secretion, i.e., blood which leaves by their veins contains different nical substances from that which enters by their ries. In many cases it may be reasonably assumed that new substances are in some degree specific for the par- lar tissue. But the idea of internal secretion has in some ances been extended beyond the limits defined by the s at our disposal. In some cases we may be guided to e extent by the structure of the organ or tissue in ques- . If it be composed of epithelial cells of a glandular racter we may reasonably be prepared to attribute to it function of internal secretion, even though the nature of secretion be quite unknown. In other cases if some stance not commonly found in, or extractable from, the ues of the body be manufactured in a tissue or organ we strongly incline to the view that the said substance is nternal secretion, and this even if the tissue in question arts somewhat widely from the glandular type. As an mple of such a tissue may be adduced the medullary rarenal gland. Extracts of many tissues will, when cted into the blood-vessels of a living animal, cause a ering of the blood pressure. This is markedly so, for mple, in the case of the nervous tissues—but it would rash to allege that to manufacture the depressor substance ne of the functions of the nervous system. On the other d, from some organs such very exceptional substances be extracted, and such very unusual physiological cts can be produced by their administration, that we justified in interpreting these effects as an indication of function of the organ, and in regarding the substances the products of its "internal secretion." This, again, plies to the medullary suprarenal. But a typical gland ving a duct and performing "external secretion" may ssess in addition the function of "internal secretion." us the liver has, as pointed out by Claude Bernard and erred to above, besides the formation of the bile the cogenic function. It has the still further duty to render nocuous the end products of proteid metabolism. One of ese is ammonia; this is converted in the liver into urea, that the distinctly poisonous ammonia is transformed this organ into the comparatively harmless urea. This an example of what may be called a "negative internal cretion."

[2] "The matters separated from the blood by the action of a secreting organ are: 1. Substances which existed previously in the blood and are merely eliminated from it; such are the urea, which is excreted by the kidneys, and the lactic acid and its salts, which are components both of the urine and of the *cutaneous* perspiration. These are called excretions, the process of their separation from the blood, excretion. 2. Substances which cannot be simply separated from the blood since they do not pre-exist in it, which, on the contrary, are newly produced from the proximate components of the blood by a chemical process; such are the bile, the semen, the milk, mucus, &c. These are called 'secretions.'" Elements of Physiology, Translation by W. Baly, London, 1838, vol. i., p. 429.

[3] "Die Classe der Drüsen ist eine derjenigen, welche eine Wissenschaft in ihrer ersten Jugend leichtsinnig schafft, und welche zu begrenzen und rechtfertigen ihr in Zeiten der Reife grosse Sorgen und Mühe kostet. Man hatte anfangs nur die äussere Form im Auge und nannte jedes weiche, rundliche, gefässreiche und daher röthliche oder rothe Organ eine Drüse, und das Gewebe solcher Organe drüsig." Henle. Sömmerings Bau des Menschlichen Körpers, Band vi., p. 889.

[5] Chez les animaux, la sécrétion glycogénique est une sécrétion interne, parce qu'elle se déverse directement dans le sang. J'ai considéré le foie, tel qu'il se présente chez les animaux vertébrés élevés, comme un organe sécréteur double. Il semble réunir, en effet, deux éléments sécrétoires distincts, et il représente deux sécrétions: l'une externe, qui coule dans l'intestin, la sécrétion biliaire; l'autre interne, qui *se verse dans le sang, la sécrétion* glycogénique. *Claude* Bernard, loc. cit.

The most usually quoted example, however, of a gland hich has both an external and an internal secretion is e pancreas. A relation between diseases of the pancreas d diabetes had long been suspected,[8] but Minkowski d Mehring[9] first definitely showed that complete removal the pancreas in the dog, cat, and pig is followed by abetes having the usual symptoms of that disease in man. hat this is caused by the absence of an internal secretion proved by the facts that it does not occur if the gland be ft *in situ* and the duct tied, nor does it occur if a portion f the pancreas be grafted in some situation remote from its ormal position (e.g., underneath the skin or in the peri- oneal cavity). How the internal secretion of the pancreas ormally prevents glycosuria is not clear. We can only say hat it exerts some influence upon the carbohydrate meta- olism, either by favouring the formation of glycogen in the iver from the dextrose taken to it by the portal vein or y furthering the oxidation of dextrose in the tissues generally.[10]

The pancreas is usually considered to consist of two eparate and distinct kinds of tissue, the secreting alveoli and the islets of Langerhans,[11] and it is supposed by many writers that it is to these latter and not to the glandular lveoli that one must attribute the internally secreting unction which concerns the carbohydrate metabolism. It is lso believed by some authors that the kidney has an internal secretion. Tigerstedt and Bergmann[12] state that a substance may be extracted from the kidneys of rabbits which when injected into the veins of a living animal causes a rise of blood pressure. They conclude, therefore, that a substance, for which they suggest the name "renin," is normally secreted by the kidney into the renal blood and that this substance causes a vaso-constriction. The rise of blood pressure is not very marked or very constant. Vincent and Sheen[13] found, however, distinct evidence of the existence of a pressor substance in the kidney. Tigerstedt and Bergmann state that the substance is destroyed by boiling, and it is certainly true here as with other tissues, with the exception of suprarenal medulla and pituitary infundibulum, that if the extract is boiled one is more likely to get a depressor effect from it. Vincent and Sheen found, in fact, that one frequently obtains pressor effects from the injection of unboiled animal extracts, while the usual effect of boiled extracts is depressor. But it must be remembered that if one simply makes an extract with cold normal saline solution one has to deal with the nucleo-proteids in addition to other substances. On the first injection of such a "proteid" extract one gets a fall of blood pressure. If a second injection be made immediately one frequently gets a rise instead of a fall.[14] It is probable that this explains, at any rate to some extent, the rise obtained by Tigerstedt and Bergmann and by Vincent and Sheen with "proteid" extracts of various tissues. It is, moreover, doubtful whether these physiological or rather pharmacological results have any very important bearing upon the question of the internal secretion of the different organs.[15]

But arguments based upon experimental work of a different character have been urged in favour of the view that the kidneys have an internal secretion. In 1869 Brown-Séquard[16] had expressed the opinion that the phenomena of uræmia were in part due to "l'existence de changements chimiques morbides du sang remplaçant la sécrétion interne normale." Later in 1892 Brown-Séquard and d'Arsonval[17] showed that "le rein a une sécrétion interne d'une grande utilité." They removed both kidneys from rabbits and guinea-pigs. Then they administered to some of these by subcutaneous injection diluted juice of kidney from a normal animal of the same species, while they left others untouched. They found that those animals which had received the injection survived one or two days longer than the others. The phenomena of uræmia were of slower development in those which survived the longer, owing to treatment with kidney extract. Meyer[18] found that injections of kidney extract, of normal blood, and of renal venous blood from a normal animal have the immediate effect of checking the Cheyne-Stokes respiration which is such a striking symptom of uræmia. Vitzou[19] found that in rabbits and dogs the injection subcutaneously and intravenously of defibrinated blood from the renal vein of a normal animal prolonged the life of a nephrectomised animal in a very striking manner. Thus in one rabbit the survival was 42½ hours longer than was the case with the control, which had like the first undergone double nephrectomy. Vitzou concludes that the kidney has an important internal secretion, the absence of which plays an important part in the causation of uræmia.

In some cases, too, there is considerable reason for ascribing an internal secreting function to an organ which is not, properly speaking, a gland at all. Thus there is evidence that the testis and the ovary perform internal secretion. Brown-Séquard[20] found that subcutaneous injections of extracts of testis exercised considerable influence upon the general health as well as the muscular power and mental activity. The experiments were performed upon himself when he was 72 years of age and he describes very marked "rejuvenating" effects. It is probable that a good deal of Brown-Séquard's personal benefit under this treatment is to be attributed to suggestion. More recently Poehl[21] asserts that he has prepared a substance, *spermin*, to which he gives the formula $C_6H_{14}N_2$, which has a very beneficial effect upon the metabolism of the body. He believes that this spermin is the substance which gives to the testicular extracts prepared by Brown-Séquard their stimulating effect. He claims for this substance an extraordinary action as a physiological tonic.[22] Zoth[23] and also Pregel[24] seem to have obtained definite proof, by means of ergographic records, of the stimulating action of the testicular extracts upon the muscle-nerve apparatus in man. They find that injection causes not only an increase in the muscular work but lessens the subjective fatigue sensations.

There are, however, other reasons for thinking that the testis pours into the blood stream certain materials which are essential for the proper development and maintenance of vigour. The condition of persons in whom the testes have not descended or from whom the testes have been removed is strong evidence that, besides the function of the preparation of the specific reproductive elements, the organ has other important duties to perform. Shattock and Seligmann[25] have studied the effect of occlusion of the vasa deferentia in sheep and fowl and find that this does not hinder the full development of the secondary male characters. Since castration does hinder this development it follows that the metabolic results arising from the functions of the testis must be attributed to the elaboration of an internal secretion and its absorption into the general circulation. According to these authors the interstitial cells of the stroma have characters so unmistakeably glandular that some secreting function must be assigned to them and they may possibly be responsible for the internal secretion just referred to.

There is an important difference in the result obtained when the whole cord is ligatured from that obtained when the vas only is tied. In the former case all sexual activity comes to an end; in the latter after a short interval of time the animal remains just in the same condition as the control, although, of course, reproduction is impossible in both cases. After ligature of the vas the interstitial cells remain unaltered although the spermatogenic tissue degenerates.[26] In the case of the ovary Knauer[27] has shown that removal of the organ prevents the occurrence of the œstrous cycle but that if ovarian tissue be grafted into the muscles of the animal the "periods" commence again. This is almost positive evidence that the occurrence of the phenomenon depends upon some material manufactured in, and poured out into the blood by, the ovary and that this pouring out causes important changes in the rest of the genital system.

Within the last two or three years a considerable amount of work has been done upon the structure and functions of the corpus luteum. The idea that this body might be an organ with an internal secretion was first conceived by Gustav Born[28] who suggested that the function of the internal secretion was to subserve the fixation and development of the impregnated ovum in the uterus. This idea was never published but was bequeathed to Fraenkel[29] to work out. This author believes that not only does the corpus luteum minister to the special needs of the gravid uterus but that upon its secretory activity depends also the occurrence of the œstrous cycle. The arguments put forward are not entirely satisfactory and it is not easy to see how this author would explain the occurrence of the first œstrus in young animals.[30] The theory that the corpus luteum is a gland with an internal secretion has also been brought forward by Prenant.[31] This writer points out that morphological characters are those of a glandular apparatus without a duct; and that the cells of the corpus luteum elaborate material in their interior as has been recently described by Regaud and Policard.[32] Prenant believes th the purpose of the corpus luteum is probably to prevent ovulation in the period between successive œstrous periods or during pregnancy. This theory is supported by Sandes who worked at the formation of the corpus luteum Dasyurus. Why it should be necessary for an animal elaborate an organ having this function does not seem clear especially in view of the fact stated by Sandes[34] that t ova degenerate in the ovary and are not preserved f succeeding ovulations.

Working in conjunction with Dr. F. H. A. Marshall I have performed a series of experiments in which extracts made from ovaries in a pro-œstrous or œstrous condition were injected into a bitch at a period as remote as possible from the œstrous one. In some of these experiments a swelling of the vulva and other slight signs of the œstrous condition were induced but the results were not decisive enough to warrant us publishing them. Since then Marshall and Jolly[35] report that "heat" or a transient condition resembling it can be produced by the injection of such extracts and that when œstrous or pro-œstrous ovaries are successfully grafted into an animal previously deprived of its ovaries the condition produced is identical with a normal heat and that irrespective of the situation of the graft. These authors consider that the ovary is an organ providing an internal secretion which is elaborated by the follicular epithelial cells or by the interstitial cells of the stroma. This secretion circulating in the blood induces menstruation and heat. After ovulation, which takes place during œstrus, the corpus luteum is formed and this organ provides a further secretion whose function is essential for the changes taking place during the attachment and development of the embryo in the first stages of pregnancy.

A recently discovered and extremely interesting example of internal secretion is furnished by the mechanism of pancreatic secretion. The secretion of the pancreatic juice is normally evoked by the entrance of acid chyme into the duodenum and is proportional to the amount of acid entering.[36] This secretion does not depend on a nervous reflex and occurs when all the nervous connexions of the intestine are destroyed.[37] The contact of the acid with the epithelial cells of the duodenum causes in them the production of a body (secretin) which is absorbed from the cells by the blood current and is carried to the pancreas, where it acts as a specific stimulus to the pancreatic cells, exciting a secretion of pancreatic juice proportional to the amount of secretin present.[38] There are probably numerous other examples of this chemical interaction of certain tissues with others more or less remote and many animal processes at present attributed to nervous influences or not understood at all will in future, it may be surmised, be explained by reference to some kind of internal secretion.[39]

THE SUPRARENAL CAPSULES.

A. Effects of ablation and disease.—In considering the facts at our disposal bearing upon the probable functions of the suprarenal capsule it is in the first place essential to insist upon the dual nature of the organ. Each capsule, in fact, consists of two separate and distinct organs, developed in quite different ways, having a different histological structure, presenting different micro-chemical reactions, and characterised by totally distinct chemical and pharmacological properties.[40] Practically, all our physiological nformation has reference to the medullary portion. The ubject of the comparative anatomy and physiology cannot be treated here.[41]

[38] Bayliss and Starling, loc. cit.

[39] Starling has recently found that injection of extracts of fœtus into a virgin rabbit causes growth of the mammary glands, while such injections into a multiparous animal cause secretion of milk. He suggests the name "hormone" (from ὁρμάω = I excite or arouse) for these various substances which act as chemical messengers. See Croonian Lectures, 1905, also THE LANCET, 1905.

[40] This view is now generally accepted, but in 1896 the subject had not passed out of the realm of discussion. See Creighton, Goulstonian Lectures, 1895, Brit. Med. Jour., March 23rd, 1895; also Swale Vincent, Birmingham Medical Review, August, 1896.

Since the time of Addison,[42] who described the disease now known by his name, numerous extirpation experiments have been performed upon many kinds of animals with omewhat varying results.[43] The general result, however, is hat death takes place with great rapidity in most animals after double suprarenal removal. In all these experiments both medulla and cortex have, of course, been removed. But it is important to note that an animal may survive the removal of both suprarenal capsules. Thus the results of Brown-Séquard,[44] who found removal to be rapidly fatal, could not be confirmed by certain other workers of this period.[45] Although later work[46] seems to have confirmed in a general way the statements of Brown-Séquard, yet we cannot disregard the very considerable number of exceptions. Moore and Purinton,[47] for example, record survival of a goat for 22 days after complete removal of both suprarenal capsules and they state "survival would apparently have been indefinite, for the animal, so far as could be observed, was unaffected by the loss of the glands. It is, of course, impossible to conclude, notwithstanding the most careful post-mortem examination, that the animal did not possess *somewhere* accessory suprarenals, which vicariously took on the functions of the removed glands. Still, we are inclined to regard such a solution of the survival as improbable; certainly, there were no glands visible to us at all resembling suprarenals in either thorax or abdomen and nothing which gave a positive answer to the chemical test for the suprarenal chromogen. Any possible accessory glands must, therefore, have been either microscopic in size or situated outside the regions where their existence was to be expected."

With regard to the presence of accessory organs we must bear in mind that if the medulla is the essential or more important organ, then, strictly speaking, there are *always* accessory organs left behind after removal of the suprarenal capsules; for groups of "chromaffin cells" are found in the sympathetic ganglia of man and mammals,[48] birds, and other vertebrates. Recently, too, Zuckerkandl[49] has described what he calls "Nebenorgane des Sympathicus" in the human subject. These consist of chromaffin cells and extracts from them have the same powerful effect upon the blood pressure as have extracts of the medulla of the suprarenal capsule.[50] On the other hand, the ordinary "accessory suprarenal" consists entirely of cortex and this probably applies to those which may be found occasionally in the neighbourhood of the reproductive organs.[51] The symptoms described by most authors are almost identical with those of pronounced Addison's disease—muscular weakness, loss of appetite, loss of tone of the vascular system, and, as a primary cause of death, paralysis of the respiratory muscles. Moore and Purinton[52] working with cats found extensive ante-mortem clotting in the right heart, superior vena cava, or pulmonary artery in three out of seven experiments, and in these cases the duration of life was shorter than in those in which no such clots were found. Pigmentation of the skin has been recorded by Nothnagel[53] after crushing of the capsules and also by F. and S. Marino-Zucco[54] after inoculating the suprarenals of rabbits with "pseudo-tubercle bacillus." Tizzoni[55] also states that he has obtained skin pigmentation in rabbits.

B. General physiological effects of extracts of the suprarenal capsules: Effects of subcutaneous injections.—After sufficiently large doses of suprarenal extract injected subcutaneously we get slowed muscular movements, paresis, and finally paralysis of the limbs (hind limbs always becoming affected first), bleeding from the mouth and nostrils, hæmaturia (not observed in rabbits), breathing rapid and shallow at first, finally becoming deep and infrequent, and occasionally convulsions resembling those of asphyxia preceding death, before which the temperature often falls very low. The paralysis is central. The effects, just as those to be presently described obtained on intravenous injection, are due to the medulla of the suprarenal capsules, the cortex containing no toxic substance. The effects are specific to the suprarenals and not common to other gland extracts. The toxic material is easily eliminated in some way or other; this accounts for the large dose required and the ease with which recovery takes place. Idiosyncrasy plays a large part in the conditions. A partial immunity can be set up by giving doses insufficient to kill.[56] In 1901 Blum[57] discovered that the subcutaneous administration of extracts of the suprarenal bodies produces diabetes in rabbits and dogs.[58] Working with adrenalin, the isolated active principle of the suprarenal medulla (*vide infra*), Drummond[59] found congestion of organs and histological changes which indicate that the substance acts as a protoplasmic poison.[60]

C. Special physiological effects of extracts of the suprarenal capsules: Effects of intravenous injections.—Our knowledge of the effects of intravenous injection of suprarenal extracts dates from the discovery of Oliver and Schäfer[61] in 1894 that such injection produces a powerful action on the muscular system, especially on the muscular walls of the blood-vessels and the heart. The extracts have an action upon skeletal muscle comparable to that produced by a small dose of veratria. Upon the heart the effect differs according as the vagi are cut or uncut. When the vagi are uncut the action of the extract is to inhibit the auricular contractions, while the ventricle continues beating with an independent slow rhythm and the pulse is very slow. If the vagi are cut or if their cardiac ends be paralysed by atropine the effect on the heart is just the reverse, and this produces a rise of the blood pressure. But there is also a marked direct effect upon the arteries shown by a considerable rise of blood pressure even with uncut vagi. "But with the vagi cut or paralysed by atropine the rise can only be characterised as enormous."[62] The contraction of the arterioles is due to a peripheral action of the drug, since it takes place when the central nervous system is destroyed.[63] The effect on the blood pressure passes off in a few minutes and, according to Schäfer,[64] the most probable explanation of the disappearance of the effect seems to be that the active principle becomes packed away and eventually rendered innocuous in certain organs. That the muscles take most part in this storage is probable from the fact that the physiological effects upon the skeletal muscles are manifested for a long time after the effects upon the heart and arteries have disappeared. The physiologically active material is yielded entirely by the medulla of the capsules,[65] the cortex being inactive. It is found, too, in the bodies of elasmobranch fishes which correspond morphologically to the medulla of the mammalian organ[66] and probably in chromaffin tissue generally.[67]

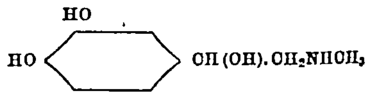
D. Mode and seat of action of suprarenal extracts.—It was shown as stated above by Oliver and Schäfer that the effects of suprarenal extract are peripheral and not central.[68] More recent investigations enable us to go a step farther. It has been shown that in mammalia if the vagi have been first paralysed with atropine suprarenal extract produces both augmented systole and acceleration of the heart.[69] Both of these effects of adrenalin may be abolished by the injection of large doses of apocodeine. Thus Dixon[70] found that in a cat half a cubic centimetre of a 1 in 30,000 solution of adrenalin increased the heart rate from 92 to 211 per minute. After the injection of 100 milligrammes of apocodeine the same injection of adrenalin now only increased the rate from 93 to 101 per minute. A futher injection of 200 milligrammes of apocodeine was then administered and caused the rate of the heart to diminish to 87 per minute. Adrenalin even in large doses now produced no acceleration and there was no augmentation of the systole. Dixon, therefore, concludes that the whole effect of suprarenal extract on the heart is a stimulation of the sympathetic nerve endings. This view is supported by the observations of Scott-Macfie[71] who found that extracts of suprarenal capsules and other tissues are without effect upon the embryonic heart, upon leucocytes, and upon cilia. Again, the experimental work of Brodie and Dixon,[72] who find that there are no vaso-motor nerves for the pulmonary arterioles and that adrenalin, when perfused through the pulmonary vessels, produces no constriction, is decidedly in favour of the theory that adrenalin acts upon nerve tissue only.[73]

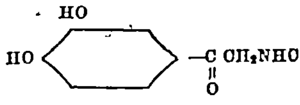
On the other hand, according to Boruttau,[74] the action is direct on somatic muscle, as it occurs in a curarised animal[75] and, according to Lewandowsky,[76] the dilatation of the pupil and other eye effects are produced by a direct action of suprarenal extract on the unstriated muscle. This was inferred from the fact that the extract was still effective after the superior cervical ganglion had been excised and the nerve fibres proceeding from it allowed to degenerate. With regard to somatic muscle, Langley[77] is inclined to accept Lewandowsky's view; while in the matter of plain muscle he put forward the generalisation that the effect of adrenalin is the same as the effect of exciting the sympathetic nerves supplying that particular tissue. Elliott[78] shows that after section of both constrictor and inhibitory nerves going to the plain muscle of the dilator pupillæ and after their degeneration for three days or ten months the plain muscle will respond to adrenalin with greater rapidity and longer persistence than does the iris the nervous relations of which are intact. Therefore, according to this writer, it cannot be that adrenalin excites any structure derived from, and dependent for its persistence on, the peripheral nerves. These different results do not accord very well together but the evidence that adrenalin acts directly on muscle and not on the nerve endings in it seems insufficient.[79] The fact that adrenalin has functionally such an intimate relation to the sympathetic nervous system is particularly interesting when we remember the accepted origin of the chromaffin tissues.[80]

According to some recent observations by Langley[81] in all cells two constituents at least must be distinguished: (1) substance concerned with carrying out the chief functions of the cells, such as contraction, secretion, the formation of special metabolic products; and (2) receptive substances especially liable to change and capable of setting the chief substance in action. According to this author nicotine, curare, atropine, pilocarpine, strychnine, and most other alkaloids, as well as the effective material of internal secretions, produce their effects by combining with the receptive substance and not by an action on axon endings if these are present, nor by a direct action on the chief substance.

E. The chemical nature of physiologically active substances.—Abel separated an alkaloid which he called *epinephrin*,[82] von Fürth isolated another substance which he called *suprarenin*,[83] but the active principle was first obtained in a crystalline form by Takamine[84] and Aldrich[85] independently. The method in both cases was the same. Very concentrated suprarenal extracts were largely freed from inactive substances by treatment with alcohol, lead acetate, &c. Then the active principle was precipitated in the form of microscopic crystals by the addition of concentrated ammonia. The precipitate was next purified by repeatedly dissolving in acid and re-precipitating with ammonia. The needles or rhombic plates so obtained Takamine called *adrenalin*. It is probable that these three names really represent one and the same substance having the empirical formula $C_9H_{13}NO_3$, and the probable structural formula is:—



If adrenalin be oxidised we get a substance having the formula:



Adrenalon

This substance, *adrenalon*, has been prepared synthetically by Friedmann,[86] Stolz,[87] and Dakin.[88] On reduction it ought, of course, to yield adrenalin, but the substances which have been obtained in this way from synthetical adrenalon seem to differ somewhat from the natural product, though they are nearly as active.[89]

F. Theories as to the function of the suprarenal capsules.—It has already been pointed out that the suprarenal capsule consists of two distinct organs, the cortex and the medulla. As the embryology of these two constituent tissues is so totally distinct, it is probable that we ought to search for a separate function for each and we have no right to assume that these functions would necessarily be intimately related each other. All the well-ascertained facts which appear point to a definite physiological significance, apply to chromaffin cells and not the greater part of the dual ly. The two chief theories are (1) the "auto-intoxication ory"; and (2) the theory of "internal secretion." The mer was first clearly stated by Abelous and Langlois[30] o performed a series of extirpation experiments upon gs. These authors found that the blood of animals dying the result of suprarenal extirpation is toxic for other imals which have recently been deprived of their capsules. e symptoms caused by this blood are said to be those of rari poisoning and the conclusion reached by Abelous d Langlois was that after suprarenal extirpation one or veral toxic substances, the products of muscular metalism, accumulate in the organism and that the function of e glands is to remove or destroy these. But, as pointed t by Schäfer,[31] it is probable that the blood of an animal ing slowly as the result of any disease, would be to some fent toxic and the toxic principles would more powerfully fect animals the resisting power of which had been lessened a recent severe operation. Further, the suprarenals produce material which has entirely different properties from those ated to be possessed by animals deprived of their capsules.

[65] Oliver and Schäfer, loc. cit.

[66] Swale Vincent, loc. cit.

[67] As already referred to above, Biedl and Wiesel have proved this for the Nebenorgane of Zuckerkandl. Cleghorn (American Journal of Physiology, vol. ii., July 1st, 1899) tested the action of extracts of sympathetic ganglia. Instead of obtaining the rise of blood pressure characteristically produced by extracts of suprarenal medulla this author got, on the contrary, a fall. This was shown by Osborne and Vincent (Proceedings of the Physiological Society, Feb. 17th, 1900; Journal of Physiology, vol. xxv., p. 9; also Journal of Physiology, 1900, vol. xxv.) to be the usual physiological action of extracts of nervous tissues in general. In sympathetic ganglia the chromaffin cells are not present in sufficient amount to produce their physiological effect. I have also repeatedly failed to obtain any physiological effect from the injection of extracts of carotid glands, but here again the difficulty is probably in isolating sufficient of the chromaffin tissue.

[68] This applies to the effect on the blood pressure. Some of the general physiological effects seem to be central (vide supra).

The "internal-secretion" theory is briefly as follows. The uprarenal capsules are continually secreting into the blood an ctive material, adrenalin, which is of benefit to the muscular ontraction and tone of the cardiac and vascular walls and ven of the skeletal muscles. Now the theory of Abelous nd Langlois was stated before the effects of injection of the xtract of suprarenal medulla were known but Abelous[32] has ecently published a paper in which he advocates the view riginally held by the joint authors. Although the theory of nternal secretion is the one which is most generally ccepted and which appears to have the balance of probbility on its side, one is bound to admit that the direct vidence in favour of the secretion of material into the lood stream is very slight. It was stated by Cybulski,[33] and epeated by Langlois[34] and Biedl,[35] that a rise of arterial lood pressure could be obtained by injection of defibriated blood obtained from the capsular vein. Schäfer[36] has een unable to confirm this and quite recently Blum[37] has enied that such results can be obtained.[38] This author, ndeed, strongly opposes the theory of internal secretion, elieving the "Entgiftung" or "auto-intoxication" theory to be the true one.[39] The difficulty is to account for the presence in the suprarenal medulla of a substance having such extraordinary physiological properties as adrenalin. The auto-intoxication theory would necessitate our assuming that this substance is a waste product soon about to be eliminated, while the internal-secretion theory supposes that it is a product of glandular activity manufactured for use in the economy. The time is not ripe for any dogmatic statement as to which is the true theory, nor, indeed, for any very definitely formulated views as to functions of the suprarenal capsules.

(To be continued.)

THE CURE OF CHRONIC SUPPURATION OF THE MIDDLE EAR WITHOUT REMOVAL OF THE DRUM OR OSSICLES OR THE LOSS OF HEARING,

WITH TEN CASES.

BY CHARLES J. HEATH, F.R.C.S. ENG.,

SURGEON TO THE THROAT HOSPITAL, GOLDEN SQUARE, LONDON.

ON Dec. 5th, 1904, I read a paper before the Otological Society of the United Kingdom, which afterwards was published in THE LANCET,[1] on "The Restoration of Hearing after Removal of the Drum and Ossicles by a Modification of the Radical Mastoid Operation for Suppurative Ear Disease" (founded on the experience of 400 operations). Early in that communication occurred the following passage: "The system I adopt, or some slight modification of it, will ultimately be adopted as a means of restoring hearing to large numbers of persons afflicted with suppurative ear disease." The modifications described below and the cases quoted, which have been examined by several otologists, will show that forecast to have had some foundation, for the change in procedure has resulted in the improvement in the hearing power of all the patients (ten) on whom this operation has been performed.

Much time was spent in studying the subject before the measures described below were put into practice. First, a glance was taken at the physiology of the mucous cavities of the ear, and their drainage was found to be dependent on one small channel, no doubt effective in health but not capable of expansion to meet the requirements of disease, and, indeed, liable to be contracted as a result of the very disease which increases the strain upon its capacity. The modifications which were introduced by disease were brought under observation, including the additional drainage of the tympanum resulting from a perforation of the membrane. The changes most commonly found in the condition of the walls and contents of the tympanum were considered as well as the possibility of recovery from these conditions. Next, the characters of the discharge came under observation and their effect on the freedom of drainage through the Eustachian tube, and especially through the aditus, should granulations or other form of obstruction arise in that passage. Observations had previously been made to the effect that the same condition had frequently appeared to be present after suppuration of three months' duration as after three or even 30 years; much instruction was derived from cases which had been seen on the operating table and these also gave hints as to possibilities. Notes had been taken concerning the methods and routes adopted by nature, either alone or assisted by surgery. Memoranda were made on all these and other points, but it is impossible even to allude to them here, much more discuss them in the small space available; therefore these remarks are mainly in abstract form and much that is important has to be excluded.

As the result of a long consideration of this subject one salient feature has always stood out prominently—namely, the importance of the cavity of the antrum—inasmuch as the persistence of the disease appeared to depend on this chamber rather than on the tympanum and therefore it became necessary to regard it as the key of the position. A few remarks concerning it will therefore not be out of place. It seemed to me that if the cavity of the antrum remained unaffected there was a good prospect that the tympanum might not become diseased past recovery and that if it became seriously diseased no treatment of the tympanum through which antral discharges must pass could be relied upon to effect a cure.

The drainage of the antrum, which from its proximity to, and liability to involve, the most vital parts should be called the danger zone of this disease, takes place through a small unyielding bony passage, the aditus, which may be obstructed more or less easily according to its size, which is variable. It does not need to be completely and rigidly obstructed for enlargement of the cavity behind it to take place. A little pressure long continued may expand it in any direction; upwards to the middle fossa less than one-eighth of an inch away, downwards and outwards to the mastoid process, backwards, or backwards and downwards to the lateral sulcus and sinus. Among the cases recorded below are examples of all these conditions. It was observed that erosion through the bone above the antrum into the middle fossa was very common and that erosion from the attic into the middle fossa above was very rare in spite of the fact that the thickness of the bone over the latter cavity was less than over the former. Surely there must needs be something to account for this fact; and it is not unreasonable to attribute it, partly or mainly, to an interference with the drainage through the aditus. Such obstruction may be slight, probably it is not often complete enough to stand pressure sufficient to cause pain, for the antrum is a sinus of but little sensibility, yet it appears to be enough to cause expansion in that direction which is most facilitated by the arrangement of the bone cells in this locality. Further, it is a cavity endowed with just those conditions which are favourable to the propagation of bacteria when they have once found entrance, and these too may bear a share in the course of this disease and should they penetrate the inflammatory protecting zone which is usually present they may travel far and wide without the process being associated with much pain to indicate the danger and thus lead to disastrous results. It is a frequent occurrence during the performance of operations on the mastoid process for chronic suppuration for observation to be made regarding the futility of expecting to cure the disease there and then exposed by any treatment through the meatus. The question may be asked, What prospect is there that the antrum will resume a healthy condition after it has once become infected and therefore the source of discharges which will by their irritating qualities lead to such an alteration in the mucous membrane of the aditus, tympanum, and Eustachian tube, as to prevent those passages allowing of proper drainage? And conversely, what chance has the tympanum of recovering a healthy condition if it has to serve as a drain for the transmission of such irritating productions of the antrum as get forced out through the aditus? It must be allowed that the prospect and the chance are not enough to be relied upon as probabilities. Then what is to be done? "Let us eliminate the antrum, the danger zone." Well, suppose the antrum eliminated and the passage of all irritating discharges from it through the tympanum stopped, what then? Is the condition of the tympanum (the attic is included) such that there is no probability of repair? My experiences lead me to the opinion that in the majority of cases it is not. This opinion is the result of personal observations of hundreds of mastoid operations and therefore of an acquaintance with the great damage to walls and contents of tympanum occasionally seen after scarlet fever and other diseases but which are fortunately not the rule; also of a knowledge of the fact that the radical operation is based on the assumption that the tympanum in chronic suppuration of the middle ear is usually in such a condition that it cannot recover health and function and must be emptied of its contents in order that the suppuration may be cured, an assumption which is surely supported neither by pathology nor clinical experience. Further, the paramount position which the radical operations hold in the estimation of otologists is a tacit acquiescence in the opinion that chronic suppuration of the middle ear is generally considered to be incurable by any other means. The various pathological conditions which may exist in the tympanum in this disease are well known but that they are frequently of a kind that prohibits any probability of recovery is not in harmony with my own observation and experience and it is these alone that have led me to the opinion, firstly, that the tympanum and its contents are not, as a rule, so far diseased as to be beyond repair; and secondly, that the condition of the Eustachian tube has a most important bearing on the result, for unless that passage be in a thoroughly efficient condition, the perforation of the membrane cannot heal nor the tympanum be restored to health. Naturally, therefore, the following conclusions were arrived at: that, given elimination of the antrum with its foul discharges and consequent improvement in the patency of the tympanum and Eustachian tube; given also operative provision of access to the tympanic membrane, for observation and treatment, and to the aditus for the purpose of carrying out the treatment described below, it was considered more than probable that the remaining tympanic disease would offer no great difficulties and that the cavity would therefore resume its health and function. Having come to these conclusions it was determined to put them into practice by instituting an operation combining these essential points and thus to learn if the before-mentioned observations were reliable and deductions well founded.

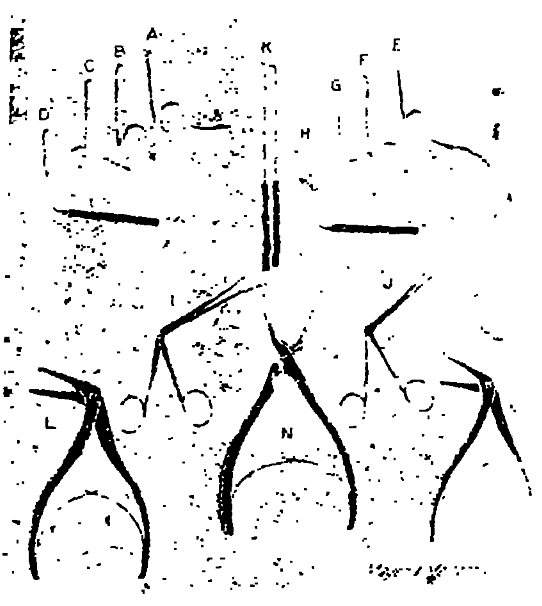
[38] If the medulla of the suprarenal capsule be really continually pouring into the suprarenal vein small quantities of adrenalin it ought to be possible, by collecting large quantities of blood coming from the organ, to get some rise of blood pressure. But the experiment is not an easy one; it must be remembered that in carnivora there is, properly speaking, no capsular vein. The vessel passing from the abdominal wall receives some tributaries from the capsule and unless special precautions are observed blood taken from the large vessel on the front of the capsule consists largely of blood which has not come from the suprarenal at all. Mr. Jolly and myself have performed two experiments in which as large a quantity of blood as possible was collected through the capsule. A saline decoction of this was then injected into a cat but in both cases instead of getting a rise of blood pressure we got a marked fall, as with an extract of any other animal substance.

[39] It may, of course, be that the true view embraces both conceptions, that the organ secretes materials which either in situ or in other regions of the body have an antitoxic action. Kohn (Prager Medicinische Wochenschrift, 1898, Jahrg. 23, No. 17; Archiv für Mikroskopische Anatomie, Band liii., 1898; Anatomischer Anzeiger, Band xv., 1899; Archiv für Mikroskopische Anatomie, Band lvi., 1900) objects to the theory of internal secretion on the part of the suprarenal medulla on morphological and histological grounds. He does not consider the chromaffin tissue to be glandular at all. I have discussed this point in a previous paper (Anatomischer Anzeiger, Band xviii., 1900, S. 71).

[1] THE LANCET, Dec. 24th, 1904, p. 1757.

Operation.—The procedure followed in the operation which has been practised in this investigation is in its opening stages similar to the early stages of the radical operation referred to above[2] but later there are modifications which will be described hereafter. The same cap can be used to obviate the need of shaving the head and most of the same instruments are suitable. The antral probes, however, must not be used to locate the antrum through the tympanum, otherwise the hearing apparatus may be damaged. After the exposure and necessary treatment of the antrum and any communicating cells and cavities (as described in the paper referred to) any granulations found in the aditus must be removed and the orifice shaped to fit the cannula (see illustration). If this passage be unusually long it may be shortened by removing bone at its posterior end and then it should be plugged to prevent the entrance of blood or bony fragments. Next, a tiny wet cotton swab should be placed on the perforation of the tympanic membrane to keep fragments from entering the cavity through that aperture. Most of the posterior part of the bony meatus must now be removed and, if necessary, even portions of the upper and lower walls, according to the size of the meatus, until complete freedom of access to the drum membrane is obtained. Any polypi or protruding granulation should be removed with the special polypus forceps (see illustration) and with these also by pressing the blades against the membrane above and below the perforation the nearest granulations can be made to protrude through the perforation, when they, too, should be caught in the forceps and removed. *These are the granulations which, if allowed to remain, would be likely to become adherent to the edge of the perforation and must therefore be removed or the membrane might afterwards become drawn inwards by contraction of those granulations.* (See Case 9, where a granulation was left in the perforation in order to see what would take place.) In removing bone near the tympanic ring the risk of injury to the facial nerve must not be forgotten. The plugs on the membrane and in the aditus should now be



A, Large cannula for right aditus. B, Medium ditto. C, Small ditto. D, Bent probe ditto. E, Large cannula for left aditus (with air bag attached). F, Medium ditto. G, Small ditto. H, Bent probe ditto. I, Large polypus or granulation forceps. J, Small ditto. K, Long slender bent probes for preventing or breaking adhesions between tympanic granulations and the membrane. L, Long bone forceps. M, Short ditto. N, Avulsion ditto.

---

[2] The Lancet, Dec. 24th, 1904, p. 1767.

oved, a cannula with a bag attached (see illustration) d in the aditus, and while the membrane is under close rvation a blast of air should be sent through the attic and panum and the effect on the drum membrane observed. If perforation appears to be too small to allow of egress of contained tympanic secretion it can be enlarged; if in unfavourable situation an entirely new opening can made for the purpose of facilitating the exit of any erial within the tympanum which is capable of expulsion powerful blast *through the aditus*. A *syringe* having n attached to the cannula, the whole tympanic passage uld next be irrigated in the same direction with some nd antiseptic, and this fluid should finally be ex- ed by the air douche and the plugs replaced in the tus and deep meatus. The cartilaginous meatal flap uld be fashioned on the same plan *as that advocated for* radical operation above referred to but should include her more of the superior quadrant in order to allow oughout the entire after treatment of that uninterrupted w of the membrane which will insure the prevention of *untoward complication*, such as an adhesion of the mbrane to a granulation. The wound behind the ear st be completely closed with sutures and all after treatnt carried on through the cartilaginous meatus, which uld be enlarged sufficiently to permit the use of a inage-tube about five-eighths of an inch in diameter, l as less bone is *removed* in this than in the radical ration this tube occupies a more oblique position. A t dressing in this operation is the best and should be con- ued in diminishing sizes as long as an external dressing is *ded.*

fter-treatment.—As the operation will have rendered the ole of the tympanic membrane visible the after-treatment thereby been made interesting, not to say instructive; it l also be found to be of shorter duration and less painful n after the radical operation, for there is generally but le of the slow-healing pars petrosa involved and the sitive tympanic cavity will not be exposed. On day following the operation the dressing and the be are removed, the entire cavity is cleansed and dried, abbed with cocaine solution, and after a short interval ed again. Then the patient is ordered to hold his nose d blow air through the ear by Valsalva's method, while effect on the membrane and perforation is carefully tched. The discharge expelled in this way is removed th tiny mops and the odour and consistency are noted; the nnula is then passed into the aditus and observation again ken of the effect on the membrane and perforation of the ssage of a blast of air from this direction. The material us expelled, which may be more purulent than that blown t by the patient's effort, should be removed, its odour and pearance noted and recorded, and if matters are pro- essing favourably the disagreeable qualities will no longer present.

The condition of the hearing power should next be tested d recorded and it will usually be found to have already proved. Finally, after seeing that the membrane is free om the liability of adhesion to any granulation, a precau- on necessary for several days, the cavity may be swabbed ith iodoform emulsion, the same tube replaced, and a essing applied. After trying several methods the following nclusion has been arrived at—viz., that after the initial eansing patients who have undergone this operation re- ver as quickly without as with fluid douches through the r, and this should not be surprising when it is remembered at air is the natural occupant of the free parts of the mpanum. Certainly no applications should be used which e likely to retard the growth of ciliated epithelium. If e aditus becomes prematurely blocked with granulations e passage of a probe will insure the freedom necessary for e use of the cannula but the probe (see illustration) should t be allowed to pass as far as the attic for fear of injury the attachments of the incus. There is no difficulty in serting the probe or cannula into the aditus without seeing , if the drainage-tube be shaped properly, kept in posi- on, and the soft parts fixed during the operation with the bject of providing this necessary access. Within a day or wo of the operation the discharge will often be seen to ome mainly or entirely from the bone and soft parts and e secretions of the tympanum to have diminished to such n extent that the Eustachian tube is adequate for their emoval.

The meaning of the sounds given out by the perforation hen air is blown through the aditus is soon understood and a day or two after the operation it is usually found that nothing but mucus comes through; the sound during inflation will then probably be moist at the beginning only, for the amount of mucus being necessarily small it gets blown out at the commencement of the inflation. When passing a probe or cannula into the aditus the mucus in the perforation, and even the drum membrane itself, can be seen to bulge outwards. The granulations which at the operation were visible through the perforation shrink and in a few days disappear. May it not be presumed that those in the attic which cannot be seen will do the same? After trying various methods of after-treatment this plan through the enlarged cartilaginous meatus has been adopted as the simplest and most direct in all cases of mastoid disease when the antrum is opened, and if the lateral sinus should be situated far forward this is the only practicable route, and anyone who sees for the first time the ease and accuracy with which the after-treatment can be carried out in this way will wonder how he ever managed satisfactorily through an opening behind the ear, for then, if the meatus should happen to be small, it is impossible either to treat or to see the tympanic condition. As might be expected, the part of the wound in which the healing is most delayed is the bony cavity in the mastoid process, the aditus usually being closed, the perforation healed, and thus the hearing apparatus made safe, some time before the antral cavity has filled and granulated, but though unhealed the discharge given off by the granulations when not irritated by the contact of mucus is so trifling that a piece of wool placed in the concha to cover the tube has been found to be a sufficient dressing.

Nine of the cases, abridged details of which are given below, are numbered in the order in which the operations were performed during the four or five weeks which ended on June 17th, 1906.

CASE 1.—The patient was seven years old; sent up from the country; suppuration three months; cause unknown; no adenoids; a discharging sinus over the *mastoid* process; granulations visible in the tympanum; perforation at the back of the membrane three-sixteenths of an inch in the longest diameter.

At operation: Large cavity in mastoid process continuous with the antrum, filled with granulations and pus; granulations not removed *from* tympanum; cannula used regularly; perforation healed in 14 days. Hearing before operation watch on contact, after operation seven inches, which for this watch is excellent hearing. The patient's hearing is probably improving. She is in the country. A letter dated July 26th, 1906, says that she now hears the watch at 30 inches.

CASE 2.—The age of the patient was eight years Suppuration during whole life; foul discharge for years; polypus in meatus hiding membrane; no adenoids.

At operation: Very large antro-mastoid cavity, filled with granulations; polypus removed from meatus; large *perforation* at the back of the membrane. Granulations removed through perforation which afterwards healed in three weeks. Hearing before operation watch on contact; after operation 12 feet. Hearing equal in both ears. A remarkable result.

CASE 3.—A patient two and a half years old. Suppuration three months. Admitted with swelling behind the ear and a high temperature. Adenoids removed. Swelling and temperature abated after one week in hospital. Discharged but readmitted at the end of another week with displacement of pinna and usual acute mastoid symptoms. Temperature 100·8 F.

At operation: Large antral cavity full of pus and granulations; sinus leading to it through the cortex; perforation at the back of the membrana tympani; granulations seen in the tympanum but not removed. Perforation healed in less than one month; much improved in appearance since operation. Entire drum still visible. Hearing before operation and since, not *satisfactorily* ascertained, but hears whisper well at a distance in both ears, apparently equally, but watch tests are unreliable for both ears on account of extreme youth.

CASE 4.—*The* patient was 29 years of age. Totally deaf in the right ear; *six months'* suppuration in the left ear. *Hearing* steadily getting worse; could only hear a loud shout in the affected ear; labyrinth defective; watch not heard on contact; most of the membrane gone; fœtid discharge; much pain.

At operation: Dura mater of lateral sinus exposed close to the bony meatus, over half an inch forward of the usual position; the small antrum extended beneath the front of the lateral sinus. As to the present condition there is now no external discharge, all mucus being removed by the Eustachian tube; perforation probably too large to have healed so soon after the operation, but has contracted. Hearing before operation required a loud shout in the ear; at present the patient hears a whisper at six feet and conversation anywhere in a room. This patient was so deaf that she lost her employment and though not a favourable case for any operation an attempt was made to improve the hearing, which has succeeded. This perforation is rapidly diminishing in size.

CASE 5.—A patient aged 14 years. Nine years' suppuration after scarlet fever; most of the tense membrane gone. Adenoids removed for ear *symptoms* in April On May 17th pain and tenderness over the mastoid. Admitted to hospital; fomented; improved; discharged. Returned June 7th with tenderness and swelling over the mastoid and high temperature; granulations seen in the perforation.

At operation: Antrum deep and small, the deeper part extending beneath a very forward lateral sinus. The perforation is not yet healed on account of its large size but the drainage goes by the Eustachian tube. Hearing before the operation watch one inch, after operation eight inches; the other ear 24 inches. This perforation is steadily diminishing in size.

CASE 6.—A patient aged 40 years. Totally deaf in the right ear; six months' suppuration in the left ear. Hearing getting steadily worse and now useless. Tiny meatus; nothing to be seen through it; carious bone felt in the tympanum; labyrinth defective; watch not heard on contact. Operation performed solely with a hope of improving the hearing; whole of the mastoid process diseased and removed; membrane observed to be of only about half the usual area. The organ of hearing in this patient is probably congenitally small. Eustachian tube is still usually found to be obstructed but can be cleared with the air bag; this prevents the perforation, which is not large, from healing. Hearing before operation needed a shout close to the ear; after operation the patient could hear conversation anywhere in the room and it was with the hope of this satisfactory improvement that the operation was performed. The disease was not acute.

CASE 7.—The patient was 18 years old. Suppuration ever since infancy. Admitted with unusually acute symptoms; displacement of ear; great pain; hard granulations entirely filling the meatus.

At operation: Enormous cavity in the mastoid process extending to the tip with pus under considerable pressure. The cavity appeared to have previously communicated with the meatus near the membrane and with the tympanum through the aditus; both routes were now blocked which accounted for the compression of the contents of the cavity. The posterior wall and the posterior part of the inner wall of the cavity pulsated freely, indicating extensive exposure of the middle and posterior fossæ of the skull. A temporary gutta-percha tissue drain was used in the lower end of the post-auricular incision for 48 hours in addition to the large drainage tube through the cartilaginous meatus. The perforation was healed in less than one month. Hearing before operation, watch on contact; afterwards seven feet; the other ear five feet. This case shows that after even prolonged suppuration the middle ear may not be in such a damaged condition as to be incapable of complete recovery.

CASE 8.—The patient was 12 years old. Suppuration several years. Admitted with an acute attack; pain, occipital and mastoid; view of the membrane obstructed by granulations.

At operation: Pus found beneath the pericranium; the mastoid disease was continuous from the antrum to the tip of the mastoid process and this space was filled with granulations and pus; the lateral sinus was freely exposed in the abscess. A temporary gutta-percha tissue drain was used in the lower end of the wound in addition to the drainage tube in the meatus. The perforation was healed 12 days after operation. Hearing before the operation, watch one inch; since operation, eight inches and is steadily improving.

CASE 9.—The patient was 49 years of age. Six months' suppuration. Admitted with all the usual acute symptoms; labyrinth involved.

At operation: The cortex was discovered to be undermined before removal. A large cavity was opened extending from the antrum to the tip of the mastoid process with the lateral sinus lying bathed in pus. A polypus in the meatus was removed but a round granulation which appeared to fit into the large perforation at the back was left to see what would result. In three or four days it had adhered to the edge of the perforation and when the patient inflated the ear the air came out through the aditus and not by the perforation; the granulation was then separated from the edge of the perforation with a probe and the patient was again told to blow. The granulation on this occasion entered the perforation, acted as a ball-valve and again obstructed the passage of air; it was left thus and has adhered and blocks this large perforation. Hearing before the operation required a loud shout and the watch was not heard on contact; since the operation half an inch; with the other ear only two and a half inches. In the best ear there is a gouty catarrh and the labyrinth also is not in good order. The patient is a hammerman and the loud ringing of the anvil may have injured the labyrinth, for it is defective on both sides and therefore deafness would surely have resulted if the radical operation had been done, for only if the labyrinthine trouble is of a transient nature is any other result probable.

CASE 10.—The patient was 29 years of age. This case should be added, although the operation was performed in 1902 in a somewhat different way, the posterior bony meatus being removed right down to the perforation, which was situated posteriorly, was crescentic, extended to the tympanic ring, upwards into Shrapnell's membrane, and was a third of an inch long. It looked as though it never would heal, for more than a quarter of the membrane appeared to have been destroyed. There had been six months' suppuration and there was a fœtid rhinitis. The discharge from the ear was very foul; there were abundant granulations and the patient was admitted with acute symptoms.

Now the membrane is intact, there is little but irregularity of the new portion to show the great extent of the disease that previously existed and, further, the patient can hear the watch at a distance of six feet. It was impossible to avoid the conviction that if the grave and extensive disease of the tympanum which this patient exhibited before operation was not incompatible with the complete recovery which followed, then there are grounds for assuming that there can be but few pathological conditions of that cavity which are. This patient's ear on account of the large size of the perforation of the membrane was a long time healing; there was, however, no otorrhœa after the operation while the aperture was closing, for the efficiency of the Eustachian tube was fully restored. It was an encouraging fact that this enormous perforation should heal at all, and that this patient completely recovered from the disease proves that elimination of the antrum was all that was required. She now has an intact hearing apparatus of excellent quality and it is probable that one or more of the only remaining three out of ten patients with, as yet, unhealed perforation will recover. (The two patients in whom the Eustachian tube is clear already show considerable reduction in the size of the tympanic perforation.) This patient (Case 10), who was exhibited at the Otological Society two and a half years ago, has been of much interest and the encouragement derived from her recovery has had much to do with the persistence of this investigation over a period of four years.

The opinion can safely be expressed that all the cases recorded above were in such a condition and had such a history as would, with the experience hitherto available, suggest to the surgeon the necessity of the radical operation, yet the results of the methods which were adopted seem to prove that in the majority, if not in all of them, the radical operation would not have resulted so favourably.

Cases 4 and 6, both delicate women with defective sight, though their tympanic perforations are not yet healed, one because it is so large and the necessary time for extensive healing has not elapsed since the operation and the other because the Eustachian tube is obstructed, are in a far better condition as to hearing and their lives are just as safe as they would be after a radical operation. The labyrinth in each of them is defective and when this is the case half a drum is better than none if the incudo-stapedial connexion is intact, for it keeps the stapes moveable and in proper position, and this will react beneficially on the round window and on the condition of the whole labyrinth.

In Cases 5, 7, and 8 the patients were admitted to the Throat Hospital, Golden-square, on account of acute symptoms, by order of my colleagues Dr. H. Lambert Lack and Mr. Charles A. Parker, who kindly handed them over to my care. My thanks are also due to our house surgeon, Dr. H. F. Shorney, for the care which he displayed in recording the notes of these cases.

The improvement in the hearing of all these patients should not be surprising when it is recognised that no part of the hearing apparatus was removed or injured at the operation and that the source of the discharges which were the cause of the tympanic irritation and deafness was taken away. The list includes all the patients who were operated upon in this manner. They may or may not show better results than are to be expected in the future. A confident opinion may be expressed that they will be improved upon but, such as they are, they are presented for consideration. These ten persons have not only been relieved of the dangers of this disease but this end has been attained without the sacrifice of the hearing of one of them and in the short period that has elapsed since the operation the perforations of the membranes of seven out of ten patients have healed.

Remarks.—What is the procedure described above? It is an adaptation to this part where the anatomical difficulties are so great of those surgical principles which are successful elsewhere. It is also a stage in the process of differentiating the larger number of patients who do not appear to require the radical operation from the smaller number who do. For what surgeon would subject a patient to a radical operation if there were a probability of a better result by any other measure. Unfortunately, hearing of such fine quality as that exhibited by several of the ten patients referred to above has never been observed to follow the radical operation. The practice of new methods usually results in increased knowledge and the proceedings above related are no exception to this rule, for they have resulted in recoveries which point to the necessity of a more searching examination of patients before proceeding to the radical measure, even though that examination may only be completed during the progress of an operation, when the necessary information should be forthcoming to show whether there is or is not a possibility of saving or restoring the hearing and this examination is urgently demanded on behalf of those persons in whom the other ear is in a condition to indicate a possible or probable failure of function, for though the removal of danger in these cases is a surgeon's first duty the preservation of the power of hearing is the second. Far be it for me to suggest that the radical operation will no longer be needed; it will still be of use for those whose hearing has been entirely destroyed or whose disease has not been found amenable to the treatment herein described which by avoiding the removal of any part essential to hearing permits such prospects of retention of the hearing power as the radical operation, associated as it is with its removal of drum and ossicles, cannot possibly afford. Confronted by the facts and experiences recorded in this communication, the otologist will no longer have the excuse of anxiety concerning the safety of the hearing to induce him to delay interference until that hearing may be destroyed, or even the patient's life in danger in consequence of which an operation may have to be immediately undertaken under such conditions that parts must be sacrificed, or have already been destroyed by the disease, which, if the operation had been performed earlier, might have been retained to the patient's great advantage. (Five of the patients referred to above were operated upon under these unfavourable conditions.) Therefore, surely it will be right in dealing with the antrum to do as the general surgeon does with regard to the appendix—that is, to recommend operation as soon as there is proof that the part is diseased and has become an abiding source of danger, r by so doing there can be no doubt that every year a eat many valuable lives will be saved.

The duration of the suppuration, which before the experi- ice gained during the years of this investigation had been nsidered of some moment, though observations of a large imber of radical operations did not support this view, has ot in itself been proved to be of much importance, for of ie three cases mentioned above, with as yet unhealed erforation though improved hearing, two of them were ases of short duration, and the third though of longer anding was the result of great damage wrought by an tack of scarlet fever.

On the other hand, the patients in Cases 2 and 7 with a istory of eight and 18 years' suppuration respectively, ery long periods, are now well, have sound ears, and the est hearing of all (hearing for watch 12 feet and seven feet) nd indicate also that duration of the disease alone does not ecessarily bring about such changes as are incompatible ith complete recovery. The hearing of the two persons Cases 4 and 6) the duration of whose suppuration was of hort standing had steadily got worse, and the watch not eing heard on contact also indicated that the labyrinth ad suffered along with other parts. Now a radical opera- ion on those patients would probably have made their earing worse, for the labyrinth must be in fine order for the earing after the radical operation to be good, and one of hese patients had previously undergone a radical operation n the other ear and the hearing on that side was *nil.* urely these points encourage the opinion that, given the ontinuity of the ossicular chain, half a drum is better for uch persons than none, as they cannot hear by the small enestræ after the radical operation, the *labyrinth is not* ufficiently sensitive, and the impressions conveyed by these mall windows are not sufficient to stimulate a defective abyrinth. In cases where the acute disease has caused reat destruction of bone and the resulting cavity in the nastoid process is large, healing may be hastened by skin rafting on Thiersch's plan through the meatus, for the avity can be thoroughly sterilised and grafting made effec- ive as soon as the leakage of mucus has been arrested by he closure of the perforation and aditus.

The appearance of the thickened and granular tympanic nucous membrane need cause no alarm; it has a protective urpose and is therefore desirable; it is of the nature of an nflammatory zone around an abscess, a strengthening of lefensive works occupied by defensive cells; and are not nflammatory conditions analogous to these, *seen everywhere* n the body where there is suppurative disease and therefore epair required? If this rational view of this disease be taken there need be no surprise at the rapid healing which followed operation in several of the cases quoted above; the tissues were vascular and ready to proceed with repair as soon as the cause of the persistence of disease was removed. As remarked above, it appeared to be reasonable to expect the tympanum to recover as soon as the cause of irritation was removed.

The presence of cerebral or extradural abscess, lateral sinus thrombosis, and the treatment which *these conditions* entail are no bar to the performance of this operation in its essential parts, and the complications which for their adequate treatment demand removal of tympanic contents, such as labyrinthine suppuration, are rarely present, and when they are the hearing will usually be found to have been already destroyed by that disease. Finally, it may be claimed that this plan eliminates disease and danger as effectually as a radical operation without destroying the power of hearing.

The results as far as appearance within the meatus is concerned would naturally be better in the persons who are subjected to operation before extensive destruction of bone has taken place as a result of acute disease; though with regard to the power of hearing there is no appreciable difference this tends to show that the acute disease was entirely behind the tympanum and is in favour of the early contention that the antrum was the key of the position. The hope may again be expressed that the experience gained by a study of these operations may induce other otologists not to allow suppuration in the ears to go on until the hearing is jeopardised nor if urgent symptoms arise—as in so many of the cases recorded above—to recommend the *radical operation*, for thereby hearing may be sacrificed, while from the foregoing it will be seen that an operation is now available which can be expected to improve the hearing in most persons and make it worse in none, and at the same time remove that risk of acute disease, to prevent which the radical operation, in spite of its risk to the hearing, is so frequently performed.

It might have been unwise to draw important conclusions from so small a number as ten operations were it not for the fact that they were so far above average severity that no other series of that number is likely to exhibit less favourable results and for the fact that the preliminary remarks and the whole design of the investigation evinced an expectation of such results

In these concluding remarks not a tithe of the important matters bearing on this subject have been touched upon which have been recorded with a view of discussion, but if enough has been said to induce other otologists to try this method of operation it is improbable that their experiences will materially differ from those given above.

Though the preliminary remarks will have shown that most of these results were foreseen, this investigation has been interesting from the very beginning. When, however, a stage was reached in which the operations were performed new phases developed which required consideration and management and it became quite engrossing. At last there was the satisfaction of knowing that it would certainly result in information which could be relied upon to place the treatment of this terrible disease on a safer and more satisfactory foundation.

The after-treatment of these cases being of such importance, and the information those duties must necessarily convey being of such value, I was constrained to undertake them myself and increased thereby the arduous nature of the task, and it is difficult even now to estimate fully the importance of this question during the short time that has elapsed since the facts were discovered

It is mainly to the unequalled opportunities afforded at the hospital to which I have the honour to belong that this work has so rapidly resulted in definite and valuable conclusions.

ON A FORM OF AMBLYOPIA IN YOUNG CHILDREN CONSEQUENT UPON INHERITED SYPHILIS.

BY SYDNEY STEPHENSON, M.B., C.M. EDIN.,
F.R.C.S. EDIN.,
OPHTHALMIC SURGEON TO THE KENSINGTON GENERAL HOSPITAL, THE
EVELINA HOSPITAL, AND THE NORTH-EASTERN HOSPITAL
FOR CHILDREN.

AMONG the more difficult cases that fall under the notice of the ophthalmic surgeon are those of amblyopia in young children. In addition to the defective history usually forthcoming from parents of the hospital class there are the innate difficulties of ophthalmoscopic examination in children of tender age, who so far from aiding our investigation, do everything they can to impede it. Then there is the uncertainty that must always surround our estimate of the degree of sight possessed by any given baby. In short, the diagnosis of few disorders calls for more patience, knowledge, and skill on the part of the surgeon than that of defective sight in babies.

The most important groups of amaurosis at present recognised in infants are four in number: first, amaurotic family idiocy (Tay and Sachs); secondly, acute cerebral amaurosis of infancy (Gay); thirdly, post-convulsive amaurosis (Ashby and Stephenson); and, last, but not least, post-meningitic amaurosis or amblyopia due to organic changes in the optic papilla and (presumably) in the optic nerve also. In addition to the foregoing, some experience of the eye diseases of children has rendered me familiar with a fifth group of cases where a form of blindness, partial or complete, is directly attributable to the action of the syphilitic virus. The condition is due immediately to opacities in the vitreous humour and remotely to a specific inflammation of the choroid or of the retina or of both those structures. The condition, of course, must be known to many others besides myself. Indeed, "specific hyalitis" has been mentioned by Mr. Jonathan Hutchinson in his memoir "On Certain Diseases of the Eye and Ear Consequent on Inherited Syphilis" (1863), and by Mr. Edward Nettleship in a communication upon Some Forms of Congenital and

Infantile Amblyopia, published in the Royal London Ophthalmic Hospital Reports for the year 1887. At the same time I may be pardoned for publishing reports of some of my own cases since, in my experience, the condition is not an altogether uncommon cause of defective sight in infants and is one that should be diagnosed early in order that specific remedies may be given a fair chance of curing the disorder. Brief details of my cases follow.

Case 1. *Amblyopia in an infant, aged seven months, who died 12 days after she was first seen, presumably from congenital syphilis.*—A. B. came under my care at the Evelina Hospital on July 19th, 1901, on account of defective sight. The mother did not know whether the baby had ever seen well but she was certain that during the last month sight had become worse. A. was the third child, and it was significant to my mind that the second child, now aged 18 months, had suffered in much the same way and was now recovering her sight. Upon examination A. B. was found to "snuffle," to be wasted, and to present a condyloma in the right groin. Her eye rolled about aimlessly and she took not the least notice of a bright object, as a gold watch. The pupils (as in most infants) responded imperfectly to atropine and no view of the details of the fundus could be obtained with the ophthalmoscope. A week later, however, opacities, especially in the anterior part of the vitreous humour, and the optic discs could be dimly recognised. The baby died on July 31st, 1901.

Case 2. *Amblyopia in a syphilitic infant, aged 11 months; considerable improvement under specific treatment.*—C. D. was admitted on March 7th, 1902, with the history that he had never seen well. Although born at term yet he was a small baby. He "snuffled" for several months and did not thrive. He was bottle-fed. The mother had been married 13 years; she had had no miscarriages. On examination I found a tolerably well-nourished baby the bridge of whose nose was markedly sunken ("saddle-bridge"). He followed the flash of the ophthalmoscopic mirror quickly and correctly. The pupils were equal but not responsive to light. The eyes (examined under chloroform) contained vitreous opacities, so numerous as to obscure all deeper details. Under treatment with mercury and chalk, one grain twice a day, the baby showed much improvement. On April 25th he was stated by his mother "to notice everything." His pupils were then responsive to light and the vitreous opacities were less marked. He had put on flesh and become good-tempered.

Case 3. *Amblyopia in a wasted infant, aged three months, associated with ptosis and spasmodic contraction of the muscles of one eye.*—E. F., a wasted "snuffling" baby, aged three months, was taken to hospital on Jan. 26th, 1904, because she was said "to take no notice of anything." She was the sixth member of the family, three members of which had died from "wasting" There was spasmodic ptosis of the left upper lid, with occasional deviation of the left eye downwards and outwards. The eyes were most difficult to examine but the right optic disc—the only one of which a good view could be obtained—was greyish-white and opacities were present in the vitreous humour of each eye.

Case 4. *Amblyopia of fluctuating type in an infant, aged two months, who had suffered from ophthalmia neonatorum; considerable improvement under mercurial tr·atment.*—G. H. was taken to hospital on Jan. 9th, 1906, with the statement that both eyes had become inflamed on the second day after birth and that since then the baby had taken little notice of things about him. On examination there was discharge from the conjunctiva, the condition of which was tolerably good. A small central macula was present on the left cornea. The pupils reacted but slightly to light. The results of the mirror test were inconclusive, the baby now taking notice of the ophthalmoscopic flash and again remaining impervious to the light stimulus. No details of the fundus could be recognised, owing to fine vitreous opacities, lying chiefly in the anterior part of the humour. The baby was treated with mercury and chalk (one grain three times a day) from Jan. 29th to March 24th, and a note made upon the latter date states that the mirror flash was well followed by the baby. The evidence of congenital syphilis in this case was not so conclusive as one could have wished but the child "snuffled" and was wasted. It would be unsafe to lay any great stress upon the craniotabes that was present since there is still a difference of opinion among competent authorities as to the precise significance of that sign.

Case 5. *Dull and fluctuating sight, due to vitreous opacities and choroiditis, in a child, aged two years, who had suffered from symptoms of congenital syphilis; improvement under prolonged treatment by mercury.*—I. K. was taken to hospital on August 22nd, 1905, on account of her sight which was stated always to have been defective. It had been noticed that her sight was worse in the morning than at other times. The eyes had never been inflamed. She was the fifth child in the family and there had been no still-births or miscarriages. When the baby was about three months old she wasted, began to look old, had an eruption on her skin, and presented bleeding ulcerations upon her lips and buttocks. She recovered after about three months' treatment by a medical man. Upon examination the child was found to walk and to talk. Her head was rather small. Her eyes were steady and her pupils were equal and responsive to light. She saw and followed with her eyes the flash of the ophthalmoscopic mirror in the darkened room. The right eye, as tested by the position of corneal reflex, had a slight convergent squint. There were fine vitreous opacities in each eye, concealing to some extent the ophthalmoscopic view of the fundus. But on careful examination with concentrated light faint but extensive choroidal changes could be recognised. Pigmentation, as usual in young children, was not a marked feature of the choroiditis. Under six months' treatment by mercury with chalk (from two to five grains per diem) the vitreous opacities disappeared and the sight became much sharper. The choroiditic changes, moreover, were seemingly brought to a standstill.

Case 6. *Amblyopia in a young child whose father admitted syphilis; nervous symptoms and loss of sight, the latter due to vitreous opacities, disseminated areolar choroiditis, and choroiditic atrophy of the optic disc; partial recovery under mercurial treatment.*—L. M., aged two and a half years, was taken to the Evelina Hospital on Nov. 14th, 1905, with the following history. The child had no definite illness until seven weeks previously, when he complained of pains in the chest, went "off his feed," began to waste, and eventually lost consciousness for a couple of days. Upon recovery it was found that he had lost the use of his left hand and leg, and about a week later that he had lost his sight which had previously been good. The father, who had been married 13 or 14 years, had suffered from syphilis seven or eight years prior to marriage. The first child, a boy, had died at six years from diphtheria; next came a miscarriage, and, lastly, the patient was born. Upon examination the child took no notice of a light and the left eye tended to diverge. The vitreous was cloudy, the optic discs were badly defined, and there were numerous patches of choroiditis in each fundus. Mercury with chalk (from three to five grains per diem) had acted so well that on April 10th, 1906, that is, after about seven months' treatment, the child noticed the mirror flash, although not always readily. The fundi showed slightly pigmented areas of choroiditis; the discs were "on the pale side"; but no vitreous opacities could be recognised.

Remarks.—The condition to which attention is drawn in this paper obviously represents a secondary manifestation of congenital syphilis (syphilis hereditaria præcox). It corresponds with the retinitis, choroiditis, or retino-choroiditis sometimes observed in acquired syphilis from, say, six months to two years after the initial sclerosis, and just as those diseases are often complicated with vitreous opacities so is the affection under notice. In both conditions, congenital and acquired, the eyes may be involved to an unequal degree but it is most unusual for one eye alone to be affected. My point about infantile amblyopia is that in babies "hyalitis" forms the leading ophthalmoscopic feature of the case, while the underlying choroiditic or retinitic lesions may be relatively insignificant or may be altogether hidden by the cloudy vitreous humour.

In my opinion, in babies a cloudy vitreous humour means one thing alone—namely, the existence of congenital syphilis. The diagnosis of the vitreous opacities, however, may be simple or the reverse. Fluctuation in sight, however, is suggestive of their existence. It is seldom, according to my experience, that one sees actual "floaters" with the ophthalmoscope. The condition usually takes the form of tiny dust-like opacities, the ophthalmoscopic effect of which is to veil or actually to conceal the details of the fundus. The latter may be seen for the first time only after the vitreous opacities have been more or less cleared by lapse of time or by the administration of mercurials.

In some cases (Nos 2, 4, 5, and 6) the hazy vitreous clears tolerably quickly under the influence of mercury. The fundus may then show few, if any, changes of a striking nature. This particular sequence appears to me to represent a primary syphilitic retinitis (or possibly a cyclitis), such as may occur in the acquired disease from six to 18 months after the chancre. Of the other cases some are strictly analogous to the much commoner disseminated choroiditis seen from one to three years after the initial sclerosis. In such patients (Case 6) the optic papilla may acquire the dirty yellowish-white hue to which the name of "choroiditic atrophy" has been applied by Sir William Gowers.

It is an interesting and remarkable feature that none of my cases of infantile amblyopia have shown any evidences, past or present, of iritis. Yet that disease was recognised and described by William Lawrence in 1830[1*] in a child, aged 16 months, whose mother was also under treatment for constitutional syphilis. Only one of the baby's eyes was affected and the inflammatory symptoms were mild. Lawrence speaks of a second case associated with wasting and eruptions and terminating in blindness.[2] William Mackenzie spoke of iritis as "not infrequently the consequence of congenital syphilis."[3] Mr. Jonathan Hutchinson, who described a series of 28 cases amongst infants aged from six weeks to 16 months, aracterised this form of iritis as "amongst the rarest of e symptoms of hereditary syphilis."[4] The disease, deed, must be exceedingly rare, for I cannot recall in my n work having recognised a single case. I agree with . George Carpenter who, in his remarkable monograph on Syphilis of Children in Everyday Practice" (1901, p. 83), ates that he has never met with a case, although as a atter of routine he has examined the eyes of hundreds syphilitic infants, and quotes Henoch also as never ving seen a case. The experience of those writers appears be borne out by that of other workers in the field of ildren's diseases.

Welbeck-street, W.

HE AURICULO-VENTRICULAR BUNDLE OF THE HUMAN HEART.

BY ARTHUR KEITH, M.D. ABERD., F.R.C.S. ENG.,
LECTURER ON ANATOMY, LONDON HOSPITAL MEDICAL COLLEGE;
AND
MARTIN W. FLACK, B.A. OXON.,
LONDON HOSPITAL.

IN a letter contributed to THE LANCET[1] one of us described the initial difficulty in finding and displaying the muscular bundle which unites the auricles and ventricles and which is now regarded as the sole pathway for the passage of the auricular wave of contraction to the ventricles. Since that letter was written we have examined over 130 human hearts and although we failed to find the bundle in some of the earlier specimens we are now confident that our failure was due to our ignorance of certain variations which may occur in its position and relationships. We are now convinced that it is an absolutely constant structure and in the properly prepared heart is big enough to be found and dissected out by knife and forceps alone; its finer structure and exact connexions require the preparation of serial microscopic sections. Through the kindness of Mr. Frank Beddard, F.R.S., prosector to the Zoological Society, and of Principal J. Y. Mackay of University College, Dundee, we have had opportunities of examining the hearts of nearly every mammalian order; in all the auriculo-ventricular bundle is present, in all it has the same position, the same connexions and distribution. We have found it in the heart of the young human fœtus in the position and form described by W. His, jun., so long ago as 1893. In seven out of nine malformed human hearts we were able to dissect out the bundle by means of knife and forceps. In a case of heart-block, described by Dr. John Hay,[2] we found that the bundle was partially obliterated at the point at which it perforates the central fibrous body of the heart. In another case of heart-block (Dr. Otto F. F. Grünbaum's) we found the bundle involved within a gumma of the septum.

Much of our pathological material we owe to Dr. J. Mackenzie of Burnley; in two of the hearts sent by him, in which there was an irregularity in the auriculo-ventricular rhythm, we found the connecting muscular bundle largely replaced by fibrous tissue. In short, all the evidence that we have been able to collect from human and comparative anatomy, from embryology, physiology, and pathology, substantiates the theory that the muscular bundle, which perforates the central fibrous body of the heart and connects together its auricular and ventricular parts, is the sole path by which the auricular wave of contraction passes to, and is distributed within, the ventricles. We take this opportunity of clearly stating that although some of our observations are new our work is in the main but a verification of the accurate and complete monograph published recently by Tawara,[3] a Japanese working in the laboratory of Professor Aschoff of Marburg.

The development of our knowledge concerning the auriculo-ventricular bundle (which, for short, may be named the *a. v.* bundle) has been one of intermittent progress. Its history may be said to begin in 1883 when Gaskell[4] proved that the auricular impulse spread to the ventricles by passing over the muscular connexion which exists between these two parts of the heart. Gaskell's work was not regarded as inapplicable to the mammalian heart until 1893; in that year Dr. A. F. Stanley Kent[5] published several papers showing that Gaskell's work may also be applied to the mammalian heart, for in it he found, contrary to all previous observations, that there is a muscular continuity between the auricular and ventricular segments of the heart. The muscular connexion, he said, was of two kinds: 1. By a direct continuity of the auricular and ventricular musculature at certain points; one of the points he specified was at the junction of the interauricular and interventricular septa of the heart; it is this point of muscular continuity which is now spoken of as the auriculo-ventricular bundle of His. 2. He described an intermediate continuity by means of a network of primitive fusiform muscular fibres which are imbedded in the fibrous tissue of the auriculo-ventricular rings of the heart. The second or intermediate muscular union described by Kent we have failed to find in the human heart.

In the same year as Kent applied Gaskell's conclusions to the mammalian heart in England W. His,[6] jun., was attacking the problem in Germany in quite another way. He studied the action of the embryonic heart and found that the auricular impulse passed to the ventricle before nerves had reached or were developed within the heart, and concluded that Gaskell's observation was true—the auricular impulses pass to the ventricle by a muscular connexion. He concluded therefore that it was an error to suppose that the muscular continuity between auricles and ventricles was completely broken during development in the hearts of birds and mammals, and that somewhere a strand of continuity must remain. He found that the muscular continuity disappeared everywhere except at one point—viz., at the junction of the auricular and ventricular septa, the point at which Kent had observed a connexion. Although the work of His, jun., was published some months later than Kent's, yet it must be owned that the German formed the more definite conception of his discovery. In the first place he concluded that the *a. v.* bundle was the sole path for the conduction of the auricular impulse to the ventricle; (2) he put his discovery to the proof of experiment and showed that section of the bundle produced discordance in the contraction of auricle and ventricle; and (3) he looked for and found and described the *a. v.* bundle in the heart of man. We have dealt with this small matter at some length because owing to the question of priority we in this country might feel inclined to replace the name of His by that of Kent.

---

[1] A Treatise on the Venereal Diseases of the Eye, p. 306. An earlier writer, Thomas Howson, described a case of mild iritis in a boy, six years of age, who had suffered from infantile syphilis, and who presented "painful enlargements in the centre of both tibiæ." (Observations on the Ophthalmia Accompanying the Secondary Forms of Lues Venerea, 1824, p. 107.) The symptoms yielded entirely to mercurial treatment.

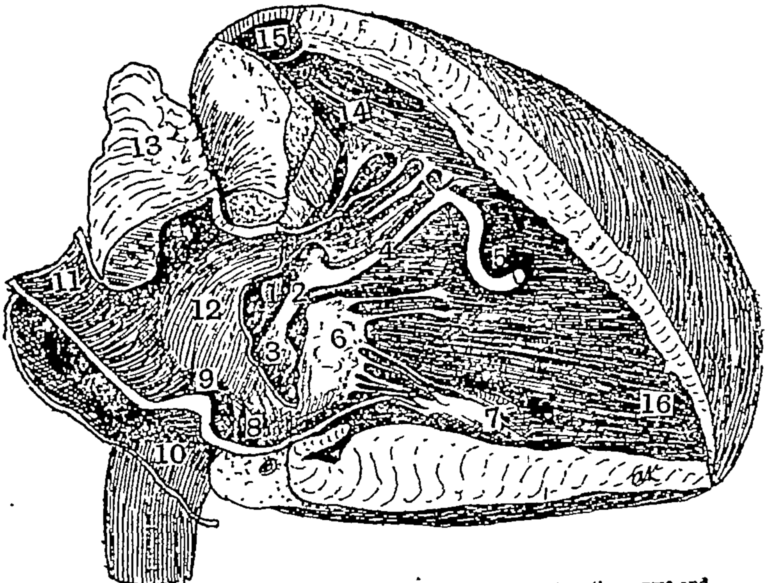
We believe that neither this bundle nor any other structure in the human body requires a personal name for its proper designation; it is only fair, if we assign the priority to the Englishman, that we should give the credit of the fuller discovery to the German.

Between the work of Gaskell and that of Kent and of His there intervened a resting period of about ten years. Another period of ten years passed before the matter was again actively pursued. Writing about a case of irregularity in the rhythm of auricles and ventricles in 1899 His[7] suggested that the lesion in such cases would be found to affect the *a. v.* bundle. Interest in the matter was undoubtedly stimulated by the exact clinical methods of Mackenzie and Wenckebach and by the experiments of Englemann. In 1904 a number of investigations were made. Retzer[8] and Braeunig[9] again verified its existence and investigated the nature of its composition. Max Humblet,[10] Hering[11] of Prague, and Erlanger[12] of Baltimore (working probably at the suggestion of Osler) set to work experimentally and confirmed the discovery of His—that the *a. v.* bundle was the sole pathway for auricular impulses across the auriculo-ventricular junction; if the bundle was partially cut or slightly compressed the impulse was delayed; if completely cut or tightly compressed the impulse was arrested or blocked, leaving the auricles and ventricles to go on beating independently. But the real advance at this time came by the application of anatomical methods. It is Tawara's merit to have shown that the *a. v* bundle described by His and seen by Kent is only the commencement of a great system which distributes the auricular impulse throughout the substance of the two ventricles. Tawara discovered that the bundle descended on the interventricular septum and was continued by ramifications to all parts of the ventricular walls; the ramifications of this system he found to be made up of Purkinje fibres, the presence of which within the heart had never been explained. In short, Tawara formulated the theory that the Purkinje system of fibres is for the conduction and distribution of the auricular impulse within the ventricles. The musculi papillares especially receive an early and liberal supply from the main divisions of the *a. v.* bundle.

The *a. v.* system of fibres has the same type of arrangement and distribution in the hearts of all mammals, but in none is this system so clearly marked as in the heart of the calf. What is seen obscurely in the human heart can be seen there as in a diagram. In Fig. 1 the right chambers of the calf's heart have been laid open; the drawing is made from a heart prepared by the Kaiserling method, by far the best we know for a naked-eye examination of this system. The cartilage within the central fibrous body of the calf's heart is shown; the endocardium of the septal wall of the right auricle and the underlying muscular fibres have been removed from the area between the cartilage and the orifice of the coronary sinus to expose an outer or superficial layer of muscle fibres belonging to the auricular canal. The fibres as they reach the central cartilage terminate in a plexus of fibres. From this plexus or network of muscular fibres commences the auriculo-ventricular bundle. The muscle fibres of the bundle and of the plexus are pale red in colour—paler, much paler, than the surrounding musculature. The bundle passes along a groove, almost a canal, in the cartilage; the canal is completed by the fibrous tissue to which the base of the septal cusp of the tricuspid valve is attached. On issuing from the central cartilage the bundle at once pierces the interventricular septum, apparently burying itself in the musculature. In the figure the bundle has been exposed by removing the overlying musculature. After a short course (one centimetre) within the upper part of the interventricular septum the *a. v* bundle divides into right and left septal divisions (see Fig. 1). The right septal division passes forwards on the septal wall of the right ventricle, almost superficial in position, until it reaches the point at which the moderator band is attached to the septum. There twigs are given off to the musculature of the septum but the main continuation of the right septal division enters the moderator band. A section across the moderator band shows the Purkinje fibres in three or four bundles; these bundles are isolated from the rest of the musculature of the moderator band by well-developed connective-tissue sheaths. Through the moderator band they reach the anterior group of musculi papillares and lateral wall of the ventricle; from there extensions to the other musculi papillares are very apparent. Beneath the endocardium a fine network of Purkinje fibres can be seen throughout the ventricle.

Fig. 1.



The right auricle and ventricle of a calf's heart exposed to show the course and connexions of the auriculo-ventricular bundle 1. Central cartilage exposed by dissection. 2. The main bundle. 3 Auricular fibres from which the main bundle arises. 4. Right septal division. 5 Moderator band. 6 Septal cusp of the tricuspid; the upper part of this cusp and the adjacent part of the infundibular cusp have been removed. 7. Posterior group of the musculi papillares. 8. Orifice of the coronary sinus. 9 So-called "tubercle of Lower" above the orifice of the inferior vena cava (10). 11. Orifice of the superior vena cava. 12. Septal wall of the right auricle. 13. Appendix of the right auricle. 14. Septal wall of the infundibulum. 15. Beginning of the pulmonary artery. 16. Apex of the right ventricle.

In Fig. 1 the bifurcation of the main bundle into right and left septal divisions is shown; in Fig. 2 is depicted the distribution of the left septal division within the left ventricle of the calf's heart. The branch appears on the septal wall of the ventricle about two centimetres below the aortic orifice; just below the aortic orifice the bundle is buried beneath a thick layer of muscle (cut through in Fig. 2 to expose the bundle). This covering stratum of musculature (sub-aortic, it may be termed) is of interest, for, as will be subsequently shown, 25 per cent. of human hearts show a remnant of it. Passing down on the septal wall the left bundle branches into two or more parts, the main part descending towards the apex of the heart, but before reaching that point most of its fibres enter two or three moderator bands (see Fig. 2) by which they pass to the musculi papillares and marginal wall of the left ventricle.

It was undoubtedly a study of the calf's and of the sheep's heart that led Tawara to formulate the theory that the system of fibres just described was a conducting, not a contracting, system. Its root lies in the annular and septal fibres of the right auricle; the trunk is buried in the interventricular septum; its branches and twigs are distributed to all parts.

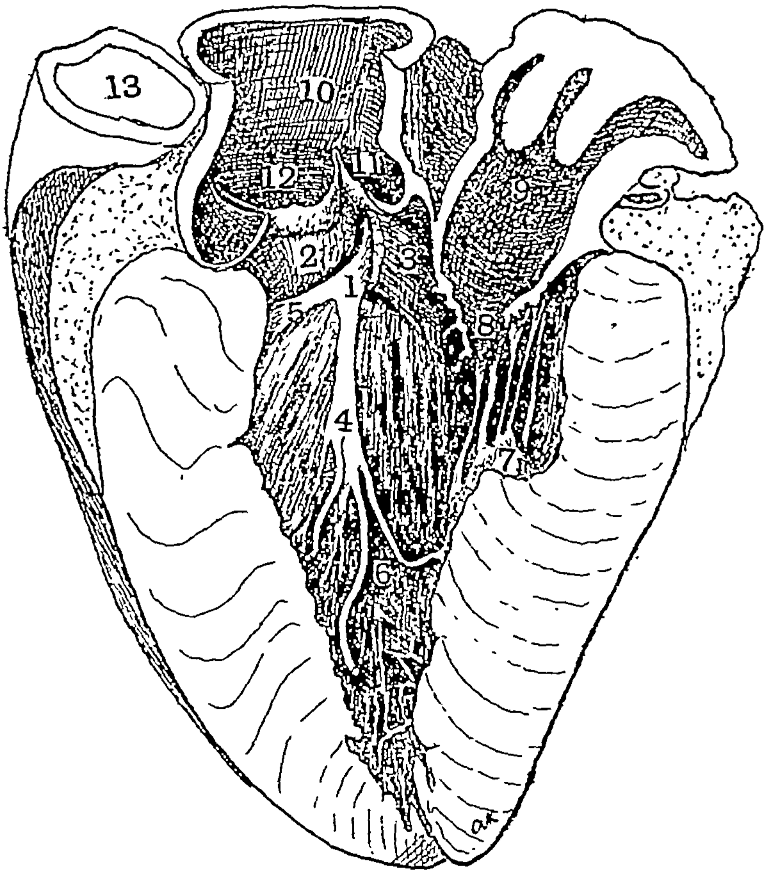
of the heart; the muscle fibres which make up the ramifications of this system (not the main bundle) are of the peculiar Purkinje type; these fibres, until they reach their terminations and join the ordinary musculature, are isolated by special fibrous sheaths. Further, when these other circumstances are taken into consideration—(1) that the systole of the ventricles is not a peristaltic contraction spreading from auricular to aortic orifices but a coördinated simultaneous contraction of the entire ventricular part of the heart; (2) that physiologists have postulated the presence of a muscular connexion between auricles and ventricles for the transmission of the auricular impulse; and (3) that the Purkinje fibres were until now of unknown significance—when all these circumstances are taken into consideration Tawara's theory commends itself to anatomists and physiologists alike as a satisfactory explanation of the presence and arrangement of the Purkinje system. The early and liberal supply of these fibres to the musculi papillares is a point to be noted. So clearly marked is the conducting system in the heart of the ruminant that one marvels how its presence and its continuity with the *a. v.* bundle have escaped notice until now.

FIG. 2.



The left ventricle of a calf's heart exposed to show the course and distribution of the left septal division of the auriculo-ventricular bundle. 1. Left septal division appearing on the upper part of the septal wall of the left ventricle. 2, 3 The sub-aortic mass of musculature divided to show the passage of the bundle from the right side of the heart. 4, 5. Branches of the left septal division. 6. Free muscular "moderator" bands containing prolongations of the bundle. 7. Septal or mesial group of musculi papillares; this group receives one of the free bundles. 8. Mitral valve. 9 Left auricle. 10. Aorta laid open. 11. Non-coronary cusp of aortic valve. 12. Right coronary cusp. 13. Pulmonary artery.

In the human heart the Purkinje system is not so clearly differentiated as in the sheep's heart but there can be no doubt, as may be seen from Figs 3 and 4, that it is present and exactly identical in its position and arrangement. In the heart shown in Fig. 3 both auricles have been removed and the right ventricle has been laid open by the removal of its lateral wall. Part of the coronary sinus (8, Fig. 3) has been left attached to the base of the left ventricle; some of the annular fibres of the right auricle, from which the *a* bundle begins, have also been left; the main bundle is rep sented, for diagrammatic effect, as a hard narrow white lin it passes forwards within the lower margin of the mer branous part of the septum and on the upper margin of t interventricular septum; the inner or mesial part of the sept cusp of the tricuspid valve has been removed to show tl bundle in this part of its course; traced backwards the bund is seen to perforate the central fibrous body of the hea which in the figure is laid open so as to show the bund joining with the fibres of the right auricle. As the bund is traced forwards in the membranous part of the septum is found to separate, as in the sheep's heart, into a right ar left septal division. The typical condition of the right sept division is shown in Fig. 3. It always passes down tl septum at the same position—viz., at the junction of tl infundibulum and sinus of the rigl ventricle. It is commonly buried the musculature of the septum, ofte in the depth of a furrow of thicken endocardium, and passes directly the anterior group of musculi papillar —the same destination as in tl sheep's heart. In the sheep's hea (Fig. 1) it reached these musculi throug the moderator band. The moderator ban of the human heart is the wide thic septal trabecula, shown at 5 in Fig. only slightly separated from the rest the interventricular septum. This gre trabecula has exactly the relationships the moderator band of the sheep's heart the classical description of a moderat band is applicable to the common typ of mammalian heart, such as th sheep's, but certainly does not hold f the human heart.

Turning to the left side of the huma heart, the left septal branch of the *a.* bundle will be found to be very apparent it is seen descending as a wide sub endocardial fillet on the septal wall o the left ventricle (Fig. 4). The mem branous part of the septum is show beneath the non-coronary and righ coronary valves of the aorta (14, 13 Fig. 4). As the main *a. v.* bundle passe forwards in the lower margin of th membranous space it gives off a con tinual stream of fibres which pass down wards in the sub-endothelial tissue o the septum and form the fillet men tioned above. The thread-like par passing from the septum to the mesial or posterior group of musculi papillares (Figs. 4 and 5) is almost constant. These threads may be two or three in number; they contain extensions of the *a. v.* bundle. The main part of the left septal division separates into two, or sometimes three, branches. The anterior of these branches passes[11] to the anterior or lateral group of musculi papillares; the posterior to the posterior or mesial group. These extensions to the musculi papillares often form free or "moderator" bands, as in the heart of the sheep and ox. Besides the branches to the musculi papillares numerous twigs go to the lateral walls of the left ventricle. In the arrangement and distribution of the *a. v.* system there is to be seen a close resemblance between the heart of man and that of the ox.

So far we have described in a general manner the course and distribution of the *a. v.* bundle, merely touching on its relationships to other parts of the heart in a cursory manner. When we came to examine microscopically the structure of the region of the heart in which the main bundle is situated,

---

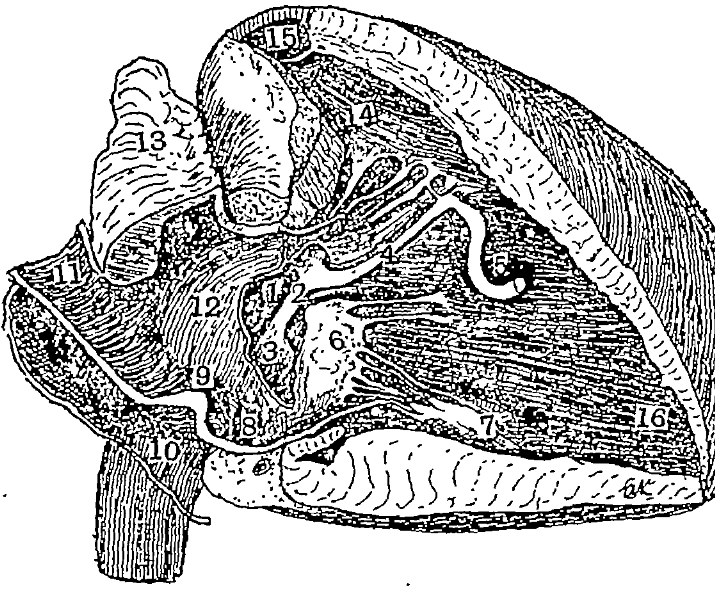
[11] At the present time there is the utmost confusion as to the nomenclature of the cusps of the aortic valve. If the terms right coronary, left coronary (above which the right and left coronary arteries arise), and non-coronary be used this confusion will be avoided.

We believe that neither this bundle nor any other structure in the human body requires a personal name for its proper designation; it is only fair, if we assign the priority to the Englishman, that we should give the credit of the fuller discovery to the German.

Between the work of Gaskell and that of Kent and of His there intervened a resting period of about ten years. Another period of ten years passed before the matter was again actively pursued. Writing about a case of irregularity in the rhythm of auricles and ventricles in 1899 His[7] suggested that the lesion in such cases would be found to affect the *a. v.* bundle. Interest in the matter was undoubtedly stimulated by the exact clinical methods of Mackenzie and Wenckebach and by the experiments of Englemann. In 1904 a number of investigations were made. Retzer[8] and Braeunig[9] again verified its existence and investigated the nature of its composition. Max Humblet,[10] Hering[11] of Prague, and Erlanger[12] of Baltimore (working probably at the suggestion of Osler) set to work experimentally and confirmed the discovery of His—that the *a. v.* bundle was the sole pathway for auricular impulses across the auriculo-ventricular junction; if the bundle was partially cut or slightly compressed the impulse was delayed; if completely cut or tightly compressed the impulse was arrested or blocked, leaving the auricles and ventricles to go on beating independently. But the real advance at this time came by the application of anatomical methods. It is Tawara's merit to have shown that the *a. v* bundle described by His and seen by Kent is only the commencement of a great system which distributes the auricular impulse throughout the substance of the two ventricles. Tawara discovered that the bundle descended on the interventricular septum and was continued by ramifications to all parts of the ventricular walls; the ramifications of this system he found to be made up of Purkinje fibres, the presence of which within the heart had never been explained. In short, Tawara formulated the theory that the Purkinje system of fibres is for the conduction and distribution of the auricular impulse within the ventricles. The musculi papillares especially receive an early and liberal supply from the main divisions of the *a. v.* bundle.

The *a. v.* system of fibres has the same type of arrangement and distribution in the hearts of all mammals, but in none is this system so clearly marked as in the heart of the calf. What is seen obscurely in the human heart can be seen there as in a diagram. In Fig. 1 the right chambers of the calf's heart have been laid open; the drawing is made from a heart prepared by the Kaiserling method, by far the best we know for a naked-eye examination of this system. The cartilage within the central fibrous body of the calf's heart is shown; *the endocardium of the* septal wall of the right auricle and the underlying muscular fibres have been removed from the area between the cartilage and the orifice of the coronary sinus to expose an outer or superficial layer of muscle fibres belonging to the auricular canal. The fibres as they reach the central cartilage terminate in a plexus of fibres. From this plexus or network of muscular fibres commences the auriculo-ventricular bundle. The muscle fibres of the bundle and of the plexus are pale red in colour—paler, much paler, than the surrounding musculature. The bundle passes along a groove, almost a canal, in the cartilage; the canal is completed by the fibrous tissue to which the base of the septal cusp of the *tricuspid* valve is attached. On issuing from the central cartilage the bundle at once pierces the interventricular septum, apparently burying itself in the musculature. In the figure the bundle has been exposed by removing the overlying musculature. After a short course (one centimetre) within the upper part of the interventricular septum the *a. v* bundle divides into right and left septal divisions (see Fig. 1). The right septal division passes forwards on the septal wall of the right ventricle, almost *superficial* in position, until it reaches the point at which the moderator band is attached to the septum. There twigs are given off to the *musculature of the* septum but the main continuation of the right septal division enters the moderator band. A section across the moderator band shows the Purkinje fibres in three or four bundles; these bundles are isolated from the rest of the musculature of the moderator band by well-developed *connective-tissue* sheaths. Through the moderator band they reach the anterior group of musculi papillares and lateral wall of the ventricle; from there extensions to the other *musculi papillares* are very apparent. Beneath the endocardium a fine network of Purkinje fibres can be seen throughout the ventricle.

FIG. 1.



The right auricle and ventricle of a calf's heart exposed to show the course and connexions of the auriculo-ventricular bundle 1. Central cartilage exposed by dissection. 2. The main bundle. 3 Auricular fibres from which the main bundle arises. 4. Right septal division. 5 Moderator band. 6 Septal cusp of the tricuspid; the upper part of this cusp and the adjacent part of the infundibular cusp have been removed. 7. Posterior group of the musculi papillares. 8 Orifice of the coronary sinus. 9. So-called "tubercle of Lower" above the orifice of the inferior vena cava (10). 11. Orifice of the superior vena cava. 12. Septal wall of the right auricle. 13. Appendix of the right auricle. 14. Septal wall of the infundibulum. 15. Beginning of the pulmonary artery. 16. Apex *of the right ventricle.*

In Fig. 1 the bifurcation of the main bundle into right and left septal divisions is shown; in Fig. 2 is depicted the distribution of the left septal division within the left ventricle of the calf's heart. The branch appears on the septal wall of the ventricle about two centimetres below the aortic orifice; *just below the aortic orifice* the bundle is buried beneath a thick layer of muscle (cut through in Fig. 2 to expose the bundle). This covering stratum of musculature (sub-aortic, *it may be termed*) is of interest, *for*, as will be subsequently shown, 25 per cent. of human hearts show a remnant of it. Passing down on the septal wall the left bundle branches into two or more parts, the main part descending towards the apex of the heart, but before reaching that point most of its fibres enter two or three moderator bands (see Fig. 2) by which they pass to the *musculi* papillares and *marginal* wall of the left ventricle.

It was undoubtedly a study of the calf's and of the sheep's heart that led Tawara to formulate the theory that *the system* of fibres just described was a conducting, not a *contracting*, system. Its root lies in the annular and *septal fibres of* the right auricle; the trunk is buried in the interventricular septum; its branches and twigs are distributed to all parts.

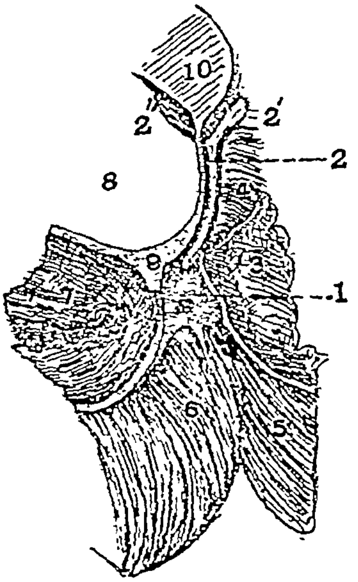
fibrous body, with which the base of the mitral valve is continuous (Fig. 4). Viewed from the right side the membranous space appears rather complicated (see Fig. 3). Its triangular shape may still be recognised; the base is formed by the upper margin of the interventricular septum, the anterior margin by the right coronary cusp (Fig. 3) and the right wall of the infundibulum, the posterior boundary by the non-coronary cusp (Fig. 3, 12), and the central fibrous body. On the right aspect the pars membranacea shows three distinct parts: one in the septal wall of the right auricle (auricular part), another in the right ventricle under the base of the septal cusp (ventricular part), and a third above both auricle and ventricle between the right coronary and non-coronary cusps (intra-cuspidate part) (see Fig. 3, between 13 and 12).

FIG. 5.



Semi-diagrammatic representation of the central fibrous body of the heart to show its intimate connexion with the mitral valve. The auricles are cut away and the adjacent parts of the bases of the ventricle are viewed from above. 1. Central fibrous body opened out; the muscular network from which the auriculo-ventricular bundle arises is cut away; the point of perforation of a constant septal artery is shown. 2. The bundle dividing in front into right (2) and left (2') septal divisions. 3. Base of septal cusp of tricuspid valve. 4. Upper part of the interventricular septum. 5. Base of the right ventricle. 6. Base of the left ventricle. 7. Mitral valve—there is stenosis with endocardial ulceration in the part nearest to the central fibrous body; disease is spreading towards the central fibrous body. 8. Conus arteriosus of the left ventricle from which the aorta arises. 9. Continuation of the central fibrous body into the aorta and interauricular septum. 10. Interventricular septum between the infundibulum of the right ventricle and conus arteriosus of the left. Between 9 and 10 runs the pars membranacea septi, here shown in section; along it runs the main auriculo-ventricular bundle.

In the sheep's heart, and, indeed, in *most mammalian* hearts, there is no pars membranacea; the membranous septum is replaced by a *mass* of musculature which covers over and buries the *a. r.* bundle. Remnants of this subaortic musculature often occur in human hearts; an example is shown in Fig. 4, just covering the left septal division of the *a. r.* bundle under the right coronary cusp. In some human hearts the pars membranacea is partially or completely replaced by muscle which fills up the angle between the aortic cusps usually occupied by the pars membranacea septi. The functional significance of the *subaortic* musculature is unknown to us.

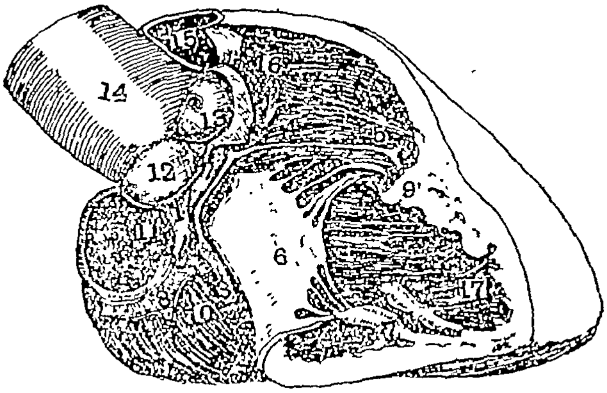
Between the *a. r.* bundle (as shown in Fig. 3) and the cut edge of the septal cusp is shown the upper margin of the interventricular septum; frequently this musculature rises up within the space normally occupied by the pars membranacea. In such cases the *a. r.* bundle is deflected for part of its course to the left side of the septum. We found that the bundle was so deflected in many of the earlier cases which we examined and in which we failed to detect the bundle in the *course of dissection*. The *right septal division* of the *a. r.* bundle leaves the main bundle by turning sharply downwards (Fig. 3); its point of origin may be termed the genu or knee. At the genu the fibres of the *a. r.* bundle appear in part, or even entirely, to terminate in a strong tendinous mass of fibrous tissue situated at the base of the right coronary cusp of the aorta. This mass of fibrous tissue has an important relationship to the *a. r.* bundle and deserves special mention, as it appears in all microscopic preparations made to expose the bundle in this region of the heart. It is much less massive than the central fibrous body but is similar in nature and function. By it the anterior fibres of the interventricular septum are united to the aorta; in systole this tendinous structure has to withstand the tension exercised on it by the heart when forcing the blood within the aorta. The tendinous fibres of this structure unite with those of the central fibrous body along the lower margin of the pars membranacea; on these uniting fibres, as on a floor, the *a. r.* bundle passes forward. In Fig. 3 the right septal division of the *a. r.* bundle is represented as a clearly *differentiated* structure but in nearly half the number of human hearts examined we were unable to follow the right septal band as a clearly differentiated continuation of the main bundle. Even in some of the hearts which were cut and examined microscopically it was only after a close search that we were able to find a strand of musculature which was clearly separated by its structure from the ordinary musculature of the septal wall.

In studying the finer structure of the *a. v.* bundle and of its ramifications in the sheep's heart two of its characters impress one—viz., (1) the character of the muscle cells of this system; and (2) the manner in which they are isolated from the ordinary musculature of the heart by sheaths of connective tissue. The network of auricular musculature in which the bundle commences is made up of peculiarly narrow muscle cells, almost fusiform in shape, united together so as to form a meshwork; the striation is less clearly marked than in the rest of the auricular *fibres*. The main bundle is made up of similar fusiform or narrow elongated fibres while its ramifications are made up of the peculiar Purkinje fibres—so different from the ordinary fibres of the ventricles. The Purkinje fibres are very large; the cells which compose them are pale; with the van Gieson stain they become of a straw yellow colour; only their outer stratum is striated; the great part of their cell body is undifferentiated protoplasm in which the nucleus is contained; wherever a part of this system appears in a microscopic preparation it is at once recognised. It is sometimes said that these Purkinje fibres are embryonic in character—undifferentiated cells. If by embryonic is meant that they resemble the cardiac fibres of the heart of the embryo, then nothing could be further from the truth; if by embryonic is meant the fact that only the *superficial* stratum of the fibres are striated—the interior being undifferentiated cell substance—then in this feature they are embryonic. But in shape and *size they* are not embryonic. They are cardiac fibres which have specialised in a peculiar direction; their fibrillar structure is especially distinct.

When the finer structure of the *a. v.* bundle system is examined in the human heart the peculiar features seen so clearly in the sheep's heart can be recognised but not with the same precision. The isolation of the system by sheaths of fibrous tissue is still *present, especially* in the first stages of the bundle within the ventricles. The structure of the auricular network (situated at, and in, the central fibrous body) from *which* the bundle arises, and the main bundle itself, have the same *structure* as in the sheep but its ramifications are not made up of distinctly marked Purkinje fibres; it is very hard to distinguish the fibres of this system from the ordinary *ventricular* muscle fibres, except by reference to three *features*: (1) they *are smaller* than the usual ventricular muscle fibre; (2) they are isolated by *thick fibrous* sheaths; and (3) they stain less deeply than the ordinary musculature; *nuclei* are more numerous; large multi-nucleated fibres occur. Tawara, on the other hand, reproduces drawings of the fibres of this system of the human heart in which *the characteristic* features of the Purkinje system are clearly recognisable. *Further* and more accurate observations have convinced us that in this Tawara is right; the ramifications are mede up of cells which certainly show the Purkinje *characters*. We found, as Tawara did, that this system does not enlarge with hypertrophy of the heart or diminish in atrophy.

especially when we came to deal with pathological conditions, we found it necessary to obtain a more accurate conception of the arrangement and structure of the central part of the heart than can be obtained at present from published works. We propose now to describe the structure, arrangement, and connexions of the bundle more minutely—especially its relationship to two important parts of the heart—viz., the central fibrous body and the pars membranacea septi.

FIG. 3.

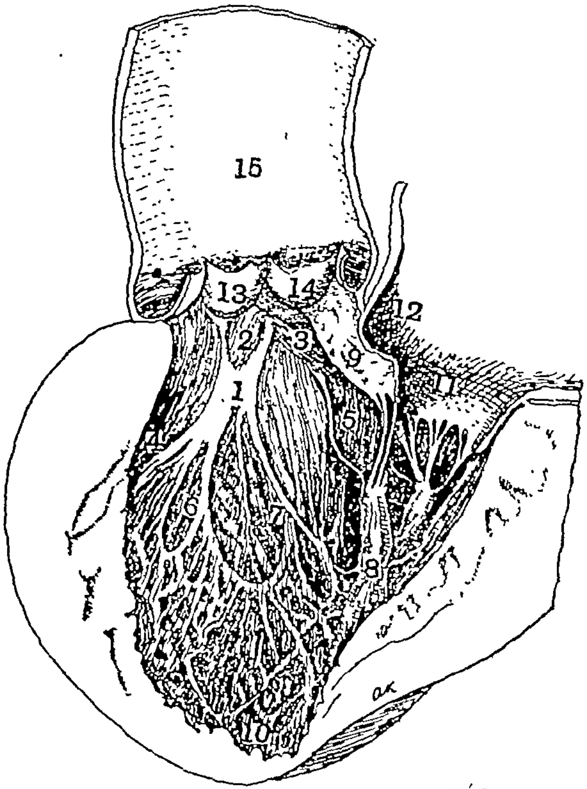


Dissection of a normal human heart to show the course and relationships of the auriculo-ventricular bundle. Both *auricles have been removed and the septal wall of the right* ventricle is exposed. 1. Central fibrous body of the heart, corresponding to the cartilage of *the calf's heart (see Fig. 1).* 2. Placed on the pars membranacea septi above the main bundle and below the attachment of the wall of the *right* auricle to the aorta. 3. Fibres of the right auricle (left *in situ*) from which the bundle takes its origin. 4. Septal wall of the infundibular part of the right ventricle placed above the right septal division of the bundle. 5. *Great trabecula* on the septal wall; part of it represents the moderator band seen in the typical mammalian heart. 6. Septal *cusp of the tricuspid; its upper part has been re*moved; above the cut edge is seen the upper margin of the interventricular septum, along which the main *bundle* runs. 7. Posterior musculi papillares. 8. Part of the coronary sinus left *in situ*. 9. Attachment of anterior group of musculi papillares into which a large part of the bundle passes. 10. Base of left ventricle. 11. Mitral valve. 12. Sinus of Valsalva of non-coronary aortic cusp. 13. Sinus *of* Valsalva of right coronary aortic cusp. 14. Aorta. 15. Beginning *of* pulmonary artery.

The central fibrous body (see Figs. 3 and 5) with which the bundle is so closely related, and in which, we have found, it is most likely to become broken by disease, is a highly complex structure. First and foremost, it is the chief tendon by which the fibres of the left ventricle are yoked to the mouth of the aorta; when the left ventricle is forcing its load within the aorta it is by this structure that the resistance is mainly borne. Both cusps of the mitral valve are continued into it and the musculi papillares, the anterior *group at least, act on it and* through it on the aorta. The musculature of the interauricular septum is implanted on it. It is attached to the aorta at the fundus of the non-coronary cusp. (See *Fig. 3.*) *It* sends off four processes, two to join the right auriculo-ventricular fibrous ring and two to join the same structure on the left side. It is thus a structure continually subjected to strain, especially in cases where the *blood pressure is high from disease of the arteries* or of the valves; our experience so far has been to find that it is in arterial disease that the central fibrous body is most likely to become affected and with its cicatrisation the bundle suffers also. Again, the central fibrous body is continuous on the one hand with the substance of the mitral valve and on the other with the septal and infundibular cusps of the tricuspid; in the heart from which Fig. 5 was drawn there were mitral stenosis and ulceration of the valves at the inner fornix of the valves. By direct spread of the inflammatory process the bundle may become affected in the central fibrous body.

The *a v* bundle has a most direct and intimate relationship to the central fibrous body. Many of the muscular fibres of the interauricular septum end on it but the fibres that most concern us are the annular fibres of the right auricle—circular fibres surrounding the right auricle just above the base of the septal cusp. These become applied to the central fibrous body which some of them perforate. Before perforation and during *perforation* they form a fine meshwork; to expose the meshwork in the central body the attachment of the septal valve of the tricuspid to that body has to be cut through. In Fig. 3 the attachment of the septal cusp to the central body has been cut through. The bundle may be then seen as an easily separated strand—from one to two millimetres wide—but very frequently it is so freely mixed with the tissue of the fibrous body that it cannot be isolated; in microscopic sections this is found to be most frequently the case. In the sheep's heart the plexus or network is very pronounced ("Knotten" Tawara names it) but in the human heart its features are not so characteristic. Yet in the human heart the *a. v.* bundle has distinctly a reticulated arrangement of fibres in and near the central fibrous body and it will be convenient to refer to it as the *a. v.* reticulum. In Fig. 5 the central fibrous body has been opened up, the muscular reticulum removed, and the *a. v.* bundle shown in front of the central fibrous body passing forwards in the pars membranacea septi. The central fibrous body is constantly perforated by a considerable artery derived from the right coronary. The point of perforation of this artery is shown in Fig. 5.

FIG. 4.



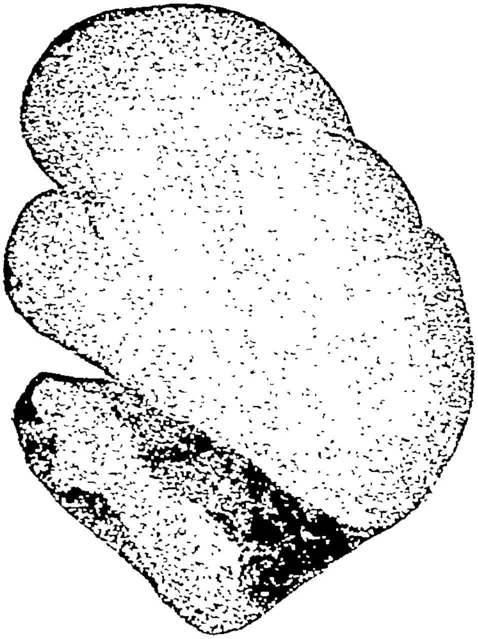
Left ventricle of the normal human *heart laid open to* show the distribution of the left division of the auriculo-ventricular bundle. 1. Bundle descending on the septal wall of the ventricle. 2. Remnant of sub-aortic musculature (see Fig. 2). 3. Constant bundle of musculature which partly covers fibres of the auriculo-ventricular bundle. 4, 5, 6, 7. Branches of the left division of the bundle. The marginal or anterior group of musculi papillares are supplied from 4. 8. The posterior or mesial musculi papillares receive prolongations from 5 and 7. 9. Anterior cusp of the mitral. 10. Apex of the left ventricle. 11. Left auriculo-ventricular orifice. 12. Left auricle. 13. Right coronary cusp of aorta. 14. Non-coronary cusp of aorta. Below 13, 14, and above 2, 3, is seen the pars membranacea septi. 15. Aorta laid open.

The *a. v.* bundle passes along the upper margin of the interventricular septum within the *fibrous tissue of the* pars membranacea septi. This structure (the pars membranacea) is roughly triangular in shape; it is commonly very extensive in hearts which have worked *against a high* arterial pressure. The best conception of its shape and position is obtained by examining it from the left side (*Fig.* 4). The base of the membranous *triangle is formed* by the upper margin *of the* interventricular septum; the posterior margin is bounded by the base of the non-coronary cusp and central starting-point of a useful discussion. I will now give an account of the case.

The patient, a man, aged 27 years, a builder's joiner, was at work on a joist on August 10th, 1904, when the joist broke and he fell through a ceiling on to the floor below, a distance of some 20 feet. He thought that he struck his left side against some projection during his fall, but he was not certain about this, though he was not rendered unconscious by the accident. This happened at 10 A.M., and he was at once taken to the Sheffield Royal Hospital, where he was admitted for a fracture of the left femur; he certainly did not at the time of admission complain of abdominal pain. He was admitted under the nominal care of Mr. R. J. Pye-Smith during his absence on a holiday, and to his kindness I am indebted for permission to publish the case. At 2 P.M. (four hours after the accident) I was called to see the patient as he was complaining of severe abdominal pain. I found him looking pale and anxious and obviously in great pain; his face was drawn and haggard and his breathing was thoracic and jerky. His pulse was 140, his temperature was 100° F., and his respirations were 50. He complained of unbearable pain in the abdomen, "like stomach-ache but more acute"; he felt sick but had not vomited and he was sure that he was going to die. He wanted to pass urine but was unable to do so; his bowels had not acted since admission. His injured leg was not troubling him. On examination the abdomen was rigid, especially in its upper part; it did not move with respiration. The liver dulness was present and there was some dulness in the epigastrium. The abdominal wall was tender on pressure, more so in the upper part. I felt sure that a catastrophe had happened inside the abdomen and that an exploration should be performed at once.

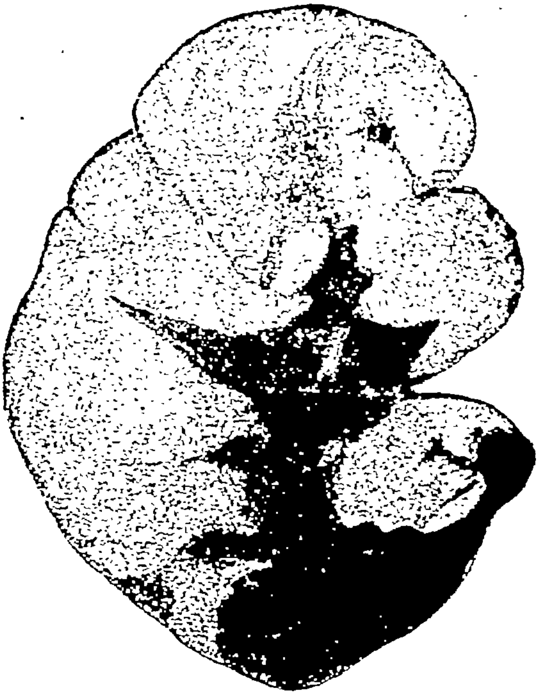
I was inclined to diagnose rupture of the intestine high up. Some delay was caused by my not being able to find any of the honorary staff (I was house surgeon at that time) and as I feared that any further waiting would be fatal, at 3.45 P.M. (five and three-quarter hours after the accident) chloroform was administered and I made a vertical incision just to the left of the umbilicus, with the level of that point as its centre. On opening the abdominal cavity neither gas nor fluid escaped nor were there any signs of commencing peritonitis, but on inserting my hand to explore the upper part of the abdomen, directly the omentum was pressed away from the anterior abdominal wall, there was an alarming rush of dark red blood. This appeared to come from the left lobe of the liver which was then examined but with some difficulty, as the blood flowed with great rapidity and continually flooded the field. As no obvious lesion of the liver was found the spleen was next palpated and I easily made out a large transverse tear, starting from the hilum and nearly separating the lower third of the organ. A long pair of artery forceps was applied to the pedicle which at once controlled the bleeding and made the rest of the operation simple. The incision was prolonged upwards and the spleen was brought round in front of the stomach, so that its anterior and external surface looked backwards and inwards, the pedicle was transfixed and ligatured with stout silk from its posterior aspect, the spleen was excised, and the blood was swabbed out of the abdominal cavity. The wound was sewn up in layers. The patient was not so well by this time, though his condition was by no means desperate; it was thought advisable to infuse three pints of saline fluid into a vein on account of his having lost so much blood. The operation took about three-quarters of an hour; on his leaving the table the patient's pulse was very frequent but quite distinct.

FIG. 1.



Antero-external aspect of spleen, showing laceration of lower pole.

FIG. 2.



Postero-internal aspect of spleen, showing laceration and stripping of capsule. The spleen has been added to the pathological museum of the University of Sheffield.

Next morning (August 11th) the patient had passed a fair night and had slept at intervals; he had vomited once after drinking some hot milk and had complained of some abdominal pain; saline enemata had been ordered every four hours but had not been well retained. His pulse was 110 and of fair tension. One grain of calomel every four hours was successful in causing his bowels to act. A catheter was passed as he was suffering from retention of urine. All went well till the 15th (the fifth day after the operation) when he suddenly began to complain of severe epigastric pain. On examination I found his pulse 120 and his temperature 101°; there was marked pulsation in the epigastrium, no rigidity of the abdominal wall, but great tenderness. I began to fear that my ligature had slipped but decided to wait as I thought the pulsation might be only communicated from the right ventricle. In a short time the patient felt better. After this progress was uneventful with two exceptions. The wound suppurated (I fear that *my aseptic* conscience must have slept during the excitement of stopping the bleeding) and the femur, which was put up in a Hodgen's splint, was found to be still ununited at the end of six weeks. However, it was put up again in the same way for another six weeks, when it united firmly with half an inch of shortening. The patient was discharged on Nov. 6th with the wound healed

From our investigations of the arrangement of the *a. v* bundle system in malformed human hearts, in the heart of the human fœtus, and in amphibian and reptilian hearts we have obtained certain facts which throw some light on its history and nature. Why should the bundle perforate the central fibrous body? The central fibrous body for the greater part is derived from the endocardial cushions of the fœtal heart, especially the posterior one. Now it was on and in the posterior endocardial cushion of the turtle's heart that we found the freest communication between the auricular and ventricular musculatures; in the heart of the turtle we found a considerable bundle of musculature of the right auricular canal ending on the posterior endocardial cushion (posterior valve of the auriculo-ventricular orifice) and freely mixing at its insertion with the origin of the sub-endocardial musculature of the ventricle. If we are right in regarding the central fibrous body of the human heart as a derivative (in part at least) of the posterior endocardial cushion, then it follows that the muscular network found at the commencement of the *a. v* bundle in the central fibrous body is the representative of the interdigitation of the auricular and ventricular musculatures in the reptilian heart.

We found that the *a. v.* bundle is differentiated and relatively massive in the heart of the human embryo of 45 millimetres long (11 weeks). In malformed hearts it was clearly derived from the circular fibres of the canal of the right auricle; it passed into the ventricle behind, and to the right of, the tissue which goes to form the central fibrous body and pars membranacea septi; on reaching the interventricular foramen it spreads out beneath the endocardium on the lower margin of that foramen and descended on both sides of the septum.

Why should the main bundle pass along the upper margin of the interventricular septum? In this position it is resting on that part of the heart which undergoes least change during the systolic changes of the heart. But there is also an embryological reason. The upper margin of the interventricular septum represents the least disturbed part of the interior of the embryonic heart. The evidence is now accumulated which shows that the interventricular septum is not developed by a process of up-growth as His supposed; its development is the result of an opposite process; the ventricles are outgrowths or bulgings of the primitive cardiac tube; the septum is that part of the tube which remains between the outgrowths; hence the upper border of the septum represents the least changed part of the lumen of the embryonic heart and it is there that the *a. v.* bundle is found.

Langendorff[15] has summarised recently the literature bearing on the physiology of this system, so that there is no need for us to deal with this matter. But there is one point which he omits and which we believe throws a side-light on the nature of this system—viz., the functional difference between pale and red musculature as we know it in the voluntary muscular system. The *a. v.* bundle is of the pale type, the ordinary cardiac musculature of the red. Dr. John Hay[16] has demonstrated that the pale voluntary muscles conduct and contract more rapidly than the red.

With regard to the clinical importance of the bundle much has been published recently, especially in connexion with cases of Stokes-Adams disease. From the interpretations placed by Wenckebach and Mackenzie upon tracings obtained in such and similar cases it has been apparent that in most of them there exist irregularities between the auricular and ventricular rhythm. The important question is, What is the cause of such irregularity? W. His, jun.,[17] writing in 1899 upon a case of the disease, opined that a lesion of the auriculo-ventricular bundle might be the cause. Recently both Hering[18] and Erlanger have entered much more fully into the subject. Both believe that a lesion of the fibres of the bundle of His can in itself account for the syndrome of events in Stokes-Adams disease. Erlanger[19] has come to the conclusion as the results of his observations upon a case under the treatment of Professor Osler. A comparison of these results with those of his experiments upon the dog's heart quoted above is exceedingly striking. In the case under observation he observed at different times all degrees of heart block. When the block was complete he found that the ventricles did not respond to influences presumably of vagus origin, whereas the auricles did. Both ventricles and auricles, however, were still under the influence of the accelerator nerves. With partial block the ventricular rate varied within certain limits proportionately to the auricular rate, but if these limits were exceeded the block became complete. Erlanger believes the syncopal attacks of Stokes-Adams disease to be due to the effect of the reduction of the ventricular rate upon the cerebral circulation. He found also that the general blood pressure is lower than normal when the heart block is complete. He considers a certain number of reported cases of the disease and comes to the conclusion that none has been described in which heart block might not have existed; indeed, all cases which have been studied by accurate methods show such to have been undoubtedly the case. Erlanger classes heart block, with and without syncopal attacks, as different phases of the same disease process.

Evidence has recently been forthcoming in support of the conclusion of Hering and Erlanger. Stengel[20] has published the result of a post-mortem examination on a case of Stokes-Adams disease. In the left side of the heart was found an atheromatous patch extending through the endocardium over the bundle of His as it passes from the auricle to the ventricle. M. E Schmoll[21] of San Francisco appears also to have discovered a lesion of the bundle in a necropsy upon a case of this disease. Recent literature also testifies to the general acceptation of this fact in non-fatal cases. Rihl[22] has published an account of five cases which he holds to be due either to partial or complete block as defined by Hering. Lichtheim[23] describes a case which he believes to be due to a lesion of the bundle produced by sclerosis of the coronary arteries. Leuchtweis[24] gives details of a case in which he diagnosed total heart block due to a lesion of the bundle. He found, as did Erlanger, that atropine did not influence the rhythm of the ventricles but caused a slight increase in auricular frequency. Finkelnburg[25] describes a case in which every third beat of the auricles caused the ventricles to contract. He believes this is due to some impairment of the conducting power of the bundle of His. Belski[26] publishes three cases of Stokes-Adams disease, two atypical and one typical. He comes to the conclusion that in each case the explanation lies in the fact that "a Stannius experiment has been performed by nature." Belski makes no reference to the bundle of His but from a careful study of his tracings and from what we now know to be the explanation of Stannius's experiment we can say that in each of these cases a lesion of the bundle of His probably existed. Whether, of course, a lesion of these fibres exists in every case of Stokes-Adams disease is still open to question. His, jun., thinks that in some cases the same phenomena can be produced by lesions of the vagi. In any case sufficient has been written here to show the great importance clinically of the auriculo-ventricular bundle.

A SUCCESSFUL CASE OF SPLENECTOMY FOR RUPTURE OF THE SPLEEN;

WITH REMARKS ON THE DIAGNOSIS AND TREATMENT OF THIS ACCIDENT.[1]

BY GRAHAM S. SIMPSON, F.R.C.S. ENG.,
ASSISTANT SURGEON TO THE SHEFFIELD ROYAL HOSPITAL.

TWO reasons have influenced me in reading this paper before you to-night: the first, that successful operations for traumatic rupture of the spleen are still uncommon; the second, the hope that some remarks that I shall make on the diagnosis and treatment of this accident may form the

[1] A paper read before the Clinical Society of London on Nov. 10th, 1905.

The mortality of the operations for rupture of the spleen that I have collected is as follows: of 70 cases recorded since 1891 42 were operated on; of these 27 lived and 15 died, a mortality of 36 per cent. (all those not operated on died). This mortality is probably much too favourable, as some cases that have been operated on and died may not have found their way into the literature.

The causes of failure after operation are: (1) peritonitis; (2) complications, such as rupture of other solid or hollow abdominal viscera, especially the left kidney; injuries of the left pleura, as hæmothorax; and other injuries, as fracture of the base of the skull; and (3) operation performed too late. Out of 28 cases where it is stated how long after the accident the operation took place three operations were performed within the first two hours. All three died (probably very severe cases). Fourteen operations took place from three to 24 hours after the accident; 11 lived and three died. Six operations were done "the next day"; five lived and one died. Five operations were done from two to eight days after the accident, only one of which lived.

The sequelæ of the operation of splenectomy present a most interesting problem. The majority show no abnormal effect except a transient anæmia and leucocytosis which swings back to normal in about a month, and an enlargement of the lymph glands, most often the left axillary and inguinal; otherwise the patients are healthy. In two cases the patients, though pregnant at the time of operation, have gone on to term. Another patient was successfully operated on for a resulting ventral hernia. A fourth recovered from an attack of typhoid fever after losing his spleen. In five recorded cases (viz., those of Mr. C. Ballance, Mr. Bernard Pitts, Mr. J. Rutherford Morison, Mr. Heaton, and Mr. H. Burrows) a curious set of symptoms supervened on and after the tenth day; these were, progressive emaciation (one case lost 3 stones), attacks of epigastric pain, pyrexia, thirst, rapid pulse and respiration, headache, drowsiness, and irritability of temper. These cases have cleared up on the exhibition of arsenic and sheep's spleens; in one case the patient relapsed when the treatment was discontinued. Mr. Ballance has suggested that these symptoms may be due to the fact that it takes some time for the other organs of the body to take over the functions of the spleen and that it is less likely to occur in children in whom the tissues are said to be less specialised. The latter part of his theory is not supported by the ages of the five cases which I have just referred to; they were 4, 9, 16, 36, and 45 years.

Note on the blood.—Ehrlich, in his work on the blood, quotes Gurloff's experiments on excision of the spleen in guinea-pigs. The latter finds a marked increase of the lymphocytes during the first year after splenectomy, corresponding to the enlargement of the lymph glands, and a moderate eosinophilia after the first year. The blood-counts in my case show eosinophilia in the second year, but the earlier counts were probably vitiated by the occurrence of increase of neutrophiles owing to the suppuration of the wound.[2]

Blood Counts.

August 13th, 1904 (three days after admission).—Red corpuscles, 3,376,000; white corpuscles, 10,000; hæmoglobin, 60 per cent. Differential count.—Neutrophiles, 75 per cent.; small mononuclears, 13·3 per cent.; large mononuclears, 10·6 per cent.; eosinophiles, 0·5 per cent.; and *nucleated* red corpuscles, 0·6 per cent.

August 18th (eight days after admission).—Red corpuscles, 2,592,000; white corpuscles, 16,000; hæmoglobin, 60 per cent. Differential count.—Neutrophiles, 81 per cent.; small mononuclears, 12 per cent.; large mononuclears 5 per cent.; eosinophiles, 1 per cent.; and nucleated red corpuscles, 1 per cent.

August 21st (11 days after admission).—Red corpuscles, 3,480,000; white corpuscles, 44,000; hæmoglobin, 60 per cent. No differential count.

August 28th (18 days after admission).—Red corpuscles, 3,360,000; white corpuscles, 16,000; hæmoglobin, 60 per cent. Differential count.—Neutrophiles, 73·6 per cent.; small mononuclears, 13·6 per cent.; large mononuclears, 11·2 per cent.; and eosinophiles, 0·4 per cent.

Sept. 4th (25 days after admission).—Red corpuscles, 4,200,000; white corpuscles, 8000; hæmoglobin, 75 per cent. No differential count.

Sept. 11th (one month after admission).—Red corpuscles, 4,920,000; white corpuscles, 8000; hæmoglobin, 90 per cent. Differential count.—Neutrophiles, 65·5 per cent.; small mononuclears, 27·5 per cent.; large mononuclears, 5 per cent.; and eosinophiles, 2 per cent.

Sept. 25th (six weeks after admission).—Red corpuscles, 4,912,000; white corpuscles, 12,000; hæmoglobin, 90 per cent. Differential count.—Neutrophiles, 73·5 per cent.; small mononuclears, 23·5 per cent.; large mononuclears, 2·5 per cent.; and eosinophiles, 0·5 per cent.

Oct. 1st (seven weeks after admission).—Red corpuscles, 4,288,000; white corpuscles, 12,000; hæmoglobin, 80 per cent. No differential count.

Oct. 8th (eight weeks after admission).—Red corpuscles, 4,800,000; white corpuscles, 12,000; hæmoglobin, 90 per cent. No differential count.

Sept. 14th, 1905 (13 months after operation).—Red corpuscles, 4,762,000; white corpuscles, 6500. Differential counts.—Neutrophiles, 57·66; and transitionals 1·21; total 58·87 per cent.; large mononuclears, 15·32 per cent.; small mononuclears, 21·14 per cent.; eosinophiles, 3·89 per cent.; basophiles, 0·73 per cent.; and mastzellen and erythroblasts, 0.

May 5th, 1906 (21 months after operation).—Red corpuscles, 4,450,000; white corpuscles, 18,000; hæmoglobin, 80 per cent. Differential count.—Neutrophiles, 59·8; and transitionals, 1·5; total 61·3 per cent.; large mononuclears, 14·8 per cent.; small mononuclears, 19·5 per cent.; mastzellen, 0·4 per cent.; basophiles, 0·6 per cent.; and eosinophiles, 3·1 per cent.

Sheffield.

SOME UNUSUAL FORMS OF ANÆMIA IN CHILDHOOD,

WITH REMARKS ON LYMPHATIC LEUKÆMIA (LYMPHÆMIA).

BY T. R. C. WHIPHAM, M.A., M.D. OXON., M.R.C.P. LOND.,
PHYSICIAN TO OUT-PATIENTS AT THE EVELINA HOSPITAL FOR SICK CHILDREN;
AND
A. N. LEATHEM, M.R.C.S. ENG., L.R.C.P. LOND.,
BACTERIOLOGIST TO CHARING CROSS HOSPITAL; PATHOLOGIST TO THE EVELINA HOSPITAL FOR SICK CHILDREN.

THE subject of anæmia, as it occurs in childhood, is but imperfectly understood, and such diverse opinions are held as to its classification and the existence of different groups that every contribution to the subject recording varieties of anæmia not commonly met with may serve as a link in the chain towards the better understanding of this form of disease. It is for this reason that we publish the cases which form the basis of this paper. The first two tend to support our views as to the existence of an acute lymphæmia without marked leucocytosis, a fact which we consider has not been sufficiently emphasised or fully appreciated by the profession in general. In the consideration of the cases which follows the clinical histories and pathological findings our views will be found in greater detail. The third case is somewhat anomalous; to relegate it to its proper category is a matter of no little difficulty. We must therefore leave the case to speak for itself, though we append a few remarks as to the class to which we consider that it belongs.

CASE 1.[1]—The patient was a girl, aged two years and one month, who attended the Evelina Hospital on August 25th, 1905, with a history that until four days previously she had been quite well but since then she had been crying and fretful, "off her food," and constipated. In addition, she had scarcely been able to walk owing to the inguinal lymphatic glands, which were noticed to be enlarged and seemed painful; there had been no feverishness or vomiting. The patient had had bronchitis as a baby and measles one year ago. The father was healthy; the mother was "delicate." There were three healthy sisters in the family—two older and one younger. Three brothers and sisters had died in infancy from bronchitis or pneumonia. When first seen on August 25th the child was somewhat thin, fretful, and of a sallow complexion, but not anæmic. The but some separation of the fibres of the left rectus at the site of the scar.

---

[2] See Ehrlich's Histology of the Blood. Translated by Myers of Cambridge, 1900.

[1] This case was shown at the meeting of the Society for the Study of Disease in Children on Oct. 20th, 1905.

During the three months of his stay in hospital his blood was frequently examined and differential counts were made; it showed the usual changes—viz., a diminution of the red corpuscles which, however, rose to normal in a month and a leucocytosis up to 44,000 which fell to normal in three weeks. The unusual amount of leucocytosis I explain by the occurrence of suppuration. No enlargement of his lymphatic glands was noticed during the first three months but since then his left axillary and inguinal glands have several times enlarged sufficiently to be easily palpated and have again subsided. At no time has he complained of pains in his bones nor has there been any particular pain on percussing them. Nor has he shown that curious group of symptoms, described by Mr. C. A. Ballance and Mr. Bernard Pitts (to which I shall again refer), though no prophylactic treatment was adopted, such as the exhibition of arsenic, sheep's spleens, &c. With the exception of the first fortnight after operation his pulse-rate has always been normal. The only after-consequences that he shows are, first, a ventral hernia and, second, a loss of nerve which prevents him from following his former occupation of builder's joiner, an occupation which involves much climbing about roofs. He has, however, taken up the work of an insurance agent and tells me that he is doing well. My thanks are due to Dr. R. J. Bethune who assisted me at the operation, did most of the blood counts, and also gave me some valuable advice.

Remarks.—From various English sources I have collected 100 cases of rupture of the spleen. Most of the cases recorded before 1891, however, are so scantily reported as to be of little value. In the following remarks I have chiefly relied on 70 cases recorded since 1891. From the point of view of diagnosis sex and age are not of much importance; as in severe accidents generally, males are more often injured than females; in these cases four-fifths of the number were males. The age distribution is most impartial: the oldest patient was 65 years of age and the youngest was in the act of being born. This last was a case of precipitate labour in which the mother was standing at the time and the child fell to the floor. The following is the age distribution (arranged in decades):—

Years.	Number of cases.	Years.	Number of cases.
1 to 10	11	41 to 50	6
11 „ 20	18	51 „ 60	11
21 „ 30	15	Over 60	2
31 „ 40	15		

I would suggest the careful consideration of three points in making a diagnosis of ruptured spleen.

1. *The history of the accident.*—The commonest cause is a sharp blow or kick on the abdomen or side. Under this heading must be included most of the cases of falling from a height, as it will usually be found that the side was struck during the fall. This accounts for 44 per cent. Next in order of frequency is a crush or squeeze, such as cases of run-over and buffer accidents. This accounts for 32 per cent. 12 per cent. are described as due to a sudden movement or strain. These are usually grouped as spontaneous ruptures and are nearly always found to be cases of large, soft, malarial spleens. One, however, was congested from a twisted pedicle. The remaining 12 per cent. are unclassified.

2. The second point in the diagnosis is the signs of internal hæmorrhage. Shock is present in the majority of cases, either at once or within a few hours. Pallor, thirst, restlessness, and retention of urine are usually stated to have been present when they are mentioned in the reports.

3. *The localising signs.*—Abdominal pain and tenderness are very constant; they are usually most marked in the region of the spleen and I have found four cases only where these signs are stated to have been absent. Rigidity of the abdominal wall, in some cases limited to the upper half of the left rectus, is a most valuable sign when present but I was surprised to find that out of 19 cases where this physical sign is mentioned in six it was stated to have been entirely absent and in another case the abdominal wall was described as slightly rigid. This initial rigidity of the abdominal wall is succeeded in from six to 24 hours by distension of the abdomen. The demonstration of dulness in the flanks is the sign which will most surely lead one to a correct diagnosis; if, as described by Mr. Ballance, on changing the position of the patient, the dulness of the right loin disappears but not that of the left a diagnosis of rupture of the spleen or the left kidney can be safely made. I feel sure that if my attention had been drawn to Mr. Ballance's paper before I had seen my case I should have been able to diagnose it correctly. Diminution of the liver dulness has been noted in a few cases and can be explained by the distension of the abdomen or by a concomitant rupture of the stomach or small intestine. No external marks of injury are present in most cases.

From the point of view of treatment I propose to divide the cases into four groups: 1. The patient dies at once or within a few minutes of the accident. These cases hardly come within the range of surgery and I can find no cases of successful operation within the first hour. 2. The opposite extreme: the symptoms are greatly delayed. I have found instances of delay from 24 hours to 15 days; this can be accounted for by the temporary arrest of the bleeding by clotting or, in some cases, by the hæmorrhage being at first subcapsular and later bursting through the capsule. 3. The majority of cases; here the initial shock of the accident, when present, is recovered from and symptoms of hæmorrhage only show themselves after a period of from one to 24 hours. 4. A very few cases where the symptoms of rupture of the spleen have been present and have gradually passed off without operation.

Which of these groups of cases require operative measures? After careful consideration my answer is, "All." In the first group the only chance is immediate laparotomy, though I fear there is not much hope of saving the patient. The cases in the second group—viz., those of delayed bleeding—are in great danger. The clot may become displaced or the capsule may rupture from distension; and in some of them, at any rate, the secondary bleeding is very severe. I think it may be laid down as a sound surgical rule that if, after showing the signs of an intra-abdominal hæmorrhage, a patient recovers but on examination the spleen is found enlarged, an exploratory laparotomy is strongly indicated. I do not think any surgeon will dispute that the cases in the third group should be explored. The last group where the patient recovers after showing the signs of a ruptured spleen (but without obvious enlargement of the organ) I propose to include as suitable for operation for the following reason: that in two cases the effused blood has become auto-infected; in one case leading to a subdiaphragmatic abscess and a fatal result and in the other to signs of sapræmia which necessitated opening and washing out the abdominal cavity.

One question that I should very much like to hear discussed is, May one operate simply on the strength of the history of the accident? I am sure that two fatal cases of rupture of the intestine that I have seen would have recovered if that had been done; the objections to such a proceeding are sufficiently obvious.

As to the operation, a vertical incision through the rectus muscle is probably the best to start with; one is not always certain about the diagnosis and if there are no adhesions and the spleen is not enlarged everything can be done through this incision. If, on the contrary, there are adhesions between the spleen and the diaphragm the operation becomes at once one of the most hazardous in the range of surgery; in that case a transverse incision below the left costal margin will be necessary.

Of the methods employed to stop the bleeding ligature of the pedicle alone has been performed in one case where it was found impossible to excise the spleen. Suture has not, as a rule, been found satisfactory, though a successful case has recently been published. The splenic substance is so friable that this method is likely to be employed only in tears limited to the capsule. With regard to gauze-packing and tampons these are not always trustworthy and are likely to cause extensive adhesions which may lead to subsequent obstruction. This method will, I think, be the best for cases where, owing to adhesions between the spleen and the diaphragm, excision of the former is too risky a proceeding. Excision of the spleen will usually have to be performed: first, because the injury is often so severe; the organ has in many cases been found torn into two or more pieces and portions have been washed out of the pelvis; and secondly, because of the frequency with which the vessels of the pedicle are involved in the injury. Moreover, clamping the pedicle at once controls the hæmorrhage.

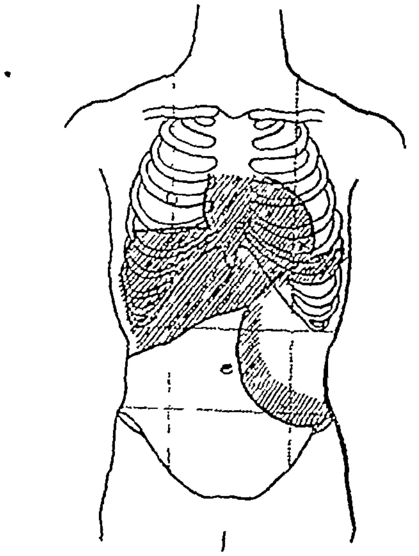
104° and the pulse was from 160 to 180. A bed was consequently again obtained for her in the hospital and she was put on iron, strychnine, and arsenic and brandy. The next day bleeding occurred from the lips and gums but no ocular hæmorrhages could be seen. A blood count showed a diminution of the red corpuscles to 1,870 000, while the leucocytes were 5600. The temperature varied between 102° and 104° and the child was very sick. On the following day (Nov. 12th) she rapidly sank and died.

The various estimations of the blood are given in Tables I. and I A.

Post mortem examination.—The body was fairly well nourished. Rigor mortis was well marked. Hypostasis was slight. There were small purpuric spots, fading slightly, on the body, face, and limbs. There were large, firm, discrete glands in the cervical, axillary, inguinal, and femoral regions. The lungs were very œdematous and presented several large areas of collapse There were a few sub-pleural hæmorrhages which were recent and not extensive. The right pleural cavity was normal but the left contained a small quantity of clear fluid and there were a few recent adhesions at the base of the left lung. The bronchial and mediastinal glands were greatly enlarged and of a red colour. There was a little bronchitis. The heart muscle was pale but not flabby; the valves were normal. There were large pale clots in both sides of the heart. Under the epicardium there were a few small hæmorrhages. The spleen was only slightly enlarged; it was soft and of a dark-red colour. The liver was pale and slightly enlarged but otherwise normal in appearance. The stomach and intestines presented no abnormal appearances. There was no obvious change in the lymphoid tissue of the intestine. The mesenteric glands were considerably enlarged, moderately firm, and reddish in colour; some were hæmorrhagic. The retro peritoneal glands were large and of a deep red colour. The bone-marrow of the ribs was pale and thicker than normal.

Microscopical sections. — Lymph glands: The lymph follicles were distinct. The lymphocytes were mostly small. The lymph sinuses appeared dilated but were nearly empty. There were a slight increase of connective tissue and slight proliferation of the endothelial cells. The large cells described by Andrewes which occur in lymphadenomatous glands could not be seen. Spleen: The Malpighian bodies were mostly ill-defined and in many of them the centre was occupied by a small, granular, structureless mass. The pulp was very crowded with red blood cells but the vessels were not distended. The lymphoid cells were mostly small. The connective tissue was increased slightly and there was a little thickening of the capsule. Liver: Microscopical sections showed very small deposits of lymphoid cells almost entirely confined to the portal canals. Films of the bone-marrow of a rib showed an enormous increase in number of the non-granular cells, the majority of them being considerably larger than a red blood corpuscle. Myelocytes and eosinophiles were present, but in very small numbers. Comparatively few red blood cells were to be seen and of them hardly any were nucleated.

CASE 2.—While the last case was still under observation a small girl, aged four years and eight months, was brought to the hospital on Nov. 3rd, 1905, on account of general pallor of three weeks' duration. Prior to that she had seemed quite well and strong and had had a good colour. Two weeks before a rash had appeared and this had become much more plentiful during the preceding few days. The appetite had been good and the child did not seem ill at first but latterly had had slight coryza and headache. She had been sick occasionally, the vomit being streaked with blood. The patient had had measles when two and a half years of age and diphtheria six months before the onset of the present symptoms. There was a history of rheumatism on both sides of the family and of the death of three brothers and sisters from bronchitis in infancy; three brothers and sisters, two of whom were older, were living and in good health. When first seen the child was irritable and very pale, the mucous membranes being blanched. The whole of the trunk and extremities were covered with discrete purpuric spots of small size; a few were apparently in the deeper tissues but for the most part they were in the skin. One was present on the anterior surface of the lower gum. The cervical, axillary, and inguinal glands on both sides were enlarged, shotty, and moveable, but not tender. In the chest there were signs of general bronchitis and of considerable dilatation of the heart. The apex beat was in the fifth space half an inch external to the nipple line and the cardiac dulness extended to the third left interspace and to just beyond the sternum on the right; a systolic murmur was audible in the pulmonary area and to a less extent at the apex but it was not conducted into the axilla. The abdomen was full, the spleen being much enlarged and soft but not tender and extending from the eighth rib in the mid-axillary line to three inches above the centre of Poupart's ligament. The liver also was big, being soft, smooth, and painless on palpation. The upper limit was the fifth rib in the right nipple line, while the lower edge could be distinctly felt four inches below the ensiform cartilage. The blood was watery and pale and showed very little tendency to coagulation. The red cells numbered 2,196,000 and the white 20 000 to the cubic millimetre; the hæmoglobin was 42 per cent. Of the leucocytes only 0·8 per cent. were polymorphonuclear, while the lymphocytes totalled 98·4 per cent., 72·6 per cent. being of the large variety. Through the kindness of Dr. F. Willcocks the patient was admitted into the hospital two days later when an examination of the eyes revealed a large, fairly recent, hæmorrhage with a central decolourised area to the outer side of the left optic disc. In the right eye there was a marked myopic crescent on the inner side of the disc but no hæmorrhage in the fundus could be seen. The pupils were dilated but there was no external abnormality in either eye. For the first few days the child was drowsy and fretful and vomited occasionally, the ejecta being streaked with blood. The bronchitis became more marked and on the 9th the patient became very restless and obviously worse. Frequent retching and occasional vomiting persisted. The temperature, which was only slightly raised on admission, now fluctuated between 100° and 102° F. accompanied by rapid pulse and respiration. On the 10th she was weaker and somewhat delirious and slight hæmorrhage occurred from the gums. She died early in the morning of Nov 11th. (See Tables II. and IIA.)



Necropsy.—A post-mortem examination was made about 15 hours after death. Rigor mortis was well marked; there was only very slight hypostasis The body was extensively marked with a purpuric rash, somewhat faded and brownish. The rash was present also on the limbs and face. The superficial lymphatic glands generally were enlarged; they were moderately firm and were not matted together. The lungs showed many hæmorrhages of various sizes, both sub-pleural and into the lung substance. The left apex was the seat of an extensive hæmorrhage. The majority of the hæmorrhages were recent but some were apparently older, the clots being decolourised and firm. There were some slight pleural adhesions. The bronchial glands were enlarged, of firm consistence, but succulent. Many of the glands contained hæmorrhages of varying extent. The thymus appeared normal but was rather large for a child of this age, weighing 12 grammes. The tonsils were large and both contained hæmorrhages. The heart was large; there was no valvular cervical, axillary, and inguinal glands were moderately enlarged on both sides, the last named being slightly tender. No enlargement of the spleen, liver, or thymus could be made out, and no extraneous cause for the glandular enlargement could be found. During the next ten days no change occurred in the physical signs but the temperature varied between 98° and 101·8° F. On Sept. 8th the inguinal glands were larger and fresh ones had appeared in both femoral regions and in the left axilla. The spleen was felt just below the ribs and the liver edge extended to nearly half way between the costal margin and the umbilicus. All the glands seemed more or less tender and those in the groin prevented the child walking. The general condition was worse and there had been some diarrhœa. The blood showed 4,736 000 red cells and 25,000 white to the cubic millimetre, with 84 per cent. of hæmoglobin. Of the white corpuscles only 2·4 per cent. were polymorphonuclear, while the lymphocytes amounted to 96·4 per cent., of which 65·9 per cent. were of the large variety. A few normoblasts were seen. A fresh gland subsequently appeared on the chest wall in the left axilla and as the inguinal and cervical glands further increased in size the patient was admitted into the hospital on Sept. 15th and the treatment with arsenic continued. The temperature kept under 100° but rose after a week with the onset of some bronchitis, the pulse-rate all along averaging from 110 to 120. On Sept. 26th an attack of herpes zoster of some severity occurred on the left side of the chest and the temperature shot up from normal to nearly 105°, dropping to normal again, however, the next day. The glandular and visceral enlargements continued unchanged and the child's general condition remained for a time the same, so she was allowed to go home at the expressed wish of her parents. On Oct. 20th an outbreak of small purpuric spots occurred over the trunk and legs and 11 days later there was left otorrhœa. On Nov. 10th the general condition was much worse and the anæmia, which had been gradually increasing, was now marked. A loud hæmic bruit was heard over the cardiac area and some bronchitic sounds were present in the lungs. The glands and abdominal viscera were unchanged but the purpura was fading. The temperature was

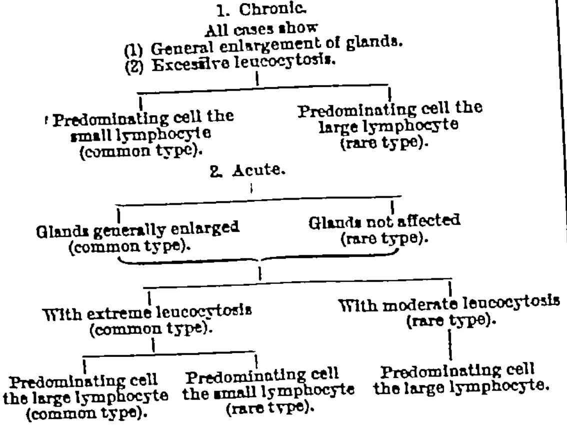
companied by extensive increase in size of the lymphatic
nds or by the absence of glandular enlargement. The
nmonest type of acute lymphæmia is that in which there
a general enlargement of the glands associated with an
treme leucocytosis, the predominating cell being the large
mphocyte. In some cases with a high grade leucocytosis,
wever, the small lymphocyte is in excess and this may be
sociated or not with general glandular enlargement. On
e other hand, in those cases in which there is a com-
aratively slight leucocytosis the predominating cell is, as
r as we know, always the large lymphocyte.

The varieties of lymphæmia may be conveniently expressed
n a tabular form thus:—



1. Chronic.
All cases show
(1) General enlargement of glands.
(2) Excessive leucocytosis.
Predominating cell the small lymphocyte (common type).
Predominating cell the large lymphocyte (rare type).
2. Acute.
Glands generally enlarged (common type).
Glands not affected (rare type).
With extreme leucocytosis (common type).
With moderate leucocytosis (rare type).
Predominating cell the large lymphocyte (common type).
Predominating cell the small lymphocyte (rare type).
Predominating cell the large lymphocyte.

A point which we consider of great pathological importance in cases of acute lymphæmia is the fact that there may be a marked general enlargement of the lymph glands or there may be little or no such enlargement. Moreover, the cases in which there is no increase in size of the lymph glands may show an enormous increase in the number of lymphocytes, generally of the large variety but occasionally of the small, while those cases, such as the two we now report, in which a well-marked and extensive glandular enlargement is present may show only a comparatively mild leucocytosis, the diagnosis in such cases depending largely on the high percentage of lymphocytes and being confirmed post mortem by the condition of the marrow and perhaps also by changes in the viscera. Normally, the lymphocytes are derived from three sources: the spleen, the lymphoid tissue throughout the body, and the marrow. In lymphocythæmia these three sources of origin may all be involved or one only, that one, which appears most important and the only one indeed the involvement of which seems absolutely necessary in the production of the disease, being the bone marrow. Ewing[11] has found that the distribution of the lesion in the marrow in cases of lymphæmia is very irregular and in the early stage appears to be focal rather than diffuse. In one acute case he found the marrow of the ribs and femur to be normal, while that of the bodies of the vertebræ showed the usual lymphoid hyperplasia. We think it highly probable that the condition of the blood bears a much more direct relation to the extent and degree of the marrow change than to the hyperplasia of the lymphoid structures. Another point in favour of this view is the fact that in chronic lymphæmia the cellular hyperplasia of the glands is found to be largely replaced by an increase of connective tissue, such change not being accompanied by any decrease in the number of lymphocytes in the blood.

The great lymphocytosis in the cases here reported was out of all proportion to that found in childhood and in the secondary anæmias common thereto. It will be remembered that at birth the mononuclear elements constitute from 50 to 75 per cent. of the total leucocytes and that at the third year the mononuclears and the polymorphonuclears are present in about equal numbers; from the eighth to tenth years and onwards the proportions assume the adult type The blood changes in these cases were also more marked than those found in lymphadenoma, for in this disease there is frequently but little change from the normal. In the later stages it is true there may be anæmia and a relative lymphocytosis but the red cells do not as a rule fall below 3,000,000 nor does the lymphocytosis reach 50 per cent. It has been stated that occasionally the leucocytes and the characters of the blood in lymphadenoma become those of a lymphatic leukæmia, though Ewing maintains that "the statement that pseudo-leukæmia may pass into leukæmia rests upon rather uncertain observations." With this we agree and we incline to the belief that those cases in which such a change is said to have occurred were in reality instances of lymphæmia from the beginning, it not having been fully realised that lymphæmia may occur without any marked increase in the number of white corpuscles.

Anæmia infantum pseudo-leukæmica (von Jaksch), a disease which must not be confounded with lymphadenoma, or Hodgkin's disease, on account of the similarity of the name with pseudo leukæmia, a synonym of the latter, likewise differs from the cases which we now record. In von Jaksch's anæmia the spleen is much enlarged and the liver moderately so, while the lymph glands do not show an increase in size comparable to that in leukæmia. The red cells are much diminished and show variations in size and shape and the deficiency in hæmoglobin common to other anæmias, but characteristic features are an excessive number of nucleated red cells and in the graver stages the presence of megaloblasts. The leucocytes number from 20,000 to 50,000 or more, the mononuclear cells forming a slight majority, while the eosinophiles may be increased up to 6 per cent.

Such diseases as scurvy and purpura hæmorrhagica can be passed over. Clinically the cases did not resemble these affections and the blood showed greater changes than are found in them. In purpura hæmorrhagica the red corpuscles are as a rule only slightly, if at all, diminished and scarcely ever fall below two and a half millions unless there is very severe hæmorrhage, while the leucocytes generally show a distinct increase, the polymorphonuclear variety greatly predominating.[12] In scurvy likewise the blood changes are those of a secondary anæmia and present no definite characteristics.

CASE 3.—A girl, aged six years, first attended the out-patient department in June, 1903, with a history of having recently become pale and being very liable to vomiting, though since an attack of measles two years previously, which was immediately followed by severe diarrhœa, she had been getting thinner and weaker and had been very excitable. She had always been a "delicate" child and attended the hospital for wasting when seven weeks old and subsequently for rickets till the age of 18 months. For the next one and a half years her health was good but at the end of that time she had an attack of pneumonia; this was followed about a year later by the measles above referred to which confined her to bed for four weeks. In the family there were three younger children, two of whom had attended for wasting but all were then well except the youngest but one who suffered with a chronic cough. The mother was anæmic but otherwise healthy and the father enjoyed good health. There was no history of any disease in the family. When first seen the child was of small physique and delicate-looking, though by no means ill nourished and showed a slight grade of anæmia. The abdomen was "large and podgy" but no visceral abnormality was discovered either there or in the chest. The bowels were constipated. She was put on a course of cod-liver oil and malt but the former had to be omitted as it induced vomiting. In December, 1903, a slight attack of bronchitis supervened. The abdomen was still large but the child's colour was good and she was said to be getting thinner. Her weight at that time was 31 pounds 2 ounces and during the next two months she was proved to lose a few ounces. During the spring of 1904 she had some return of the cough but shortly after ceased to attend until September. Her general condition had then considerably deteriorated. She was markedly anæmic and thinner than before, having gained only 4 pounds in weight during the previous eight months. A loud hæmic bruit was audible all over the cardiac area; neither the abdominal viscera nor the lymphatic structures were enlarged. The patient complained of pain in the eyes at night and occasional headache. Mr. Sydney Stephenson was accordingly asked to examine her and he reported: "Refraction = 1·25 D. of hypermetropia; fundus normal. The pallor of the fundi and of the blood in the retinal arteries and veins recalls that of some cases of leukæmia I have disease but the heart muscle was flabby and pale. There were many small hæmorrhages to be seen under the epicardium, under the endocardium, and also into the heart muscle. The pericardium contained a slight excess of fluid which was clear but stained with hæmoglobin. The stomach was normal in appearance. In the small intestine there were numerous punctiform submucous hæmorrhages, but neither Peyer's patches nor the solitary glands were enlarged or unduly prominent. Of the mesenteric glands some were normal in size, but many were enlarged, soft, and juicy, and pinkish in colour, while many showed more or less extensive hæmorrhages. The *retro-peritoneal* glands were large, soft, and of a deep pink colour. The liver weighed 26 ounces and was pale; on section no lymphoid deposits were visible to the naked eye. The spleen was considerably enlarged, weighing ten ounces; it was friable and of a dark red colour; there were no infarcts. The pancreas, kidneys, and suprarenal capsules were normal in appearance. The bone-marrow from a rib was pale pinkish in colour and thick.

---

[11] Ewing: Clinical Pathology of the Blood, second edition, p. 235.

[12] Ewing (Clinical Pathology of the Blood) describes a non infectious idiopathic purpura hæmorrhagica which is probably identical with hæmophilia. In this condition the lymphocytes may rise to 90 per cent. (Engel), 80 per cent. (Ehrlich)

Microscopic Sections.—The lymph glands showed great hyperplasia of the lymphoid elements; the outlines of the lymphatic follicles could not be clearly recognised, the normal structure of the gland being obliterated by the diffuse lymphoid proliferation. The cells were chiefly large lymphocytes. Many of the lymph sinuses were packed with lymphocytes, but some were empty. There were no increase of connective tissue and no proliferation of the endothelium. Spleen: The Malpighian bodies were few, small, and indistinct. The pulp contained large numbers of large lymphocytes and red blood cells. The vessels were not distended. The connective tissue was slightly increased, but the capsule was not thickened. Liver: There were numerous collections of lymphoid cells, some circumscribed, some diffuse. The deposits were not limited to the portal canals and connective tissue round the interlobular veins, but occurred anywhere in or round the lobules. There were many small areas of degeneration of the liver cells. Kidneys: Microscopic sections showed fairly numerous small diffuse infiltrations with lymphoid cells. These deposits were chiefly round the larger vessels and about Bowman's capsules.

Films made from the bone marrow of a rib consisted chiefly of mononuclear non-granular cells with a very small amount of protoplasm surrounding the nucleus. These cells were of two sizes, one of about the same size as a red blood corpuscle, the other nearly twice the size, the larger cells being much more numerous than the smaller. There were a few cells with large nuclei, either oval or spherical, and a considerable amount of slightly basophilic, non-granular protoplasm. Granular cells were extremely scarce. Red blood cells were not numerous and nucleated red cells were rare.

These two cases, as so often happens with rarities or abnormalities, occurred almost simultaneously in hospital practice and, as a matter of fact, died within one day of each other, though one was of 12 weeks' duration and the other of only four. As will have been seen, the course of each of the two cases was in many ways identical, while the estimations of the blood and the differential counts of the leucocytes showed a great similarity. Both patients were small girls and in each case there was a history of sudden onset of the illness, although the initial symptoms showed a slight disparity, general malaise and glandular enlargement being noticed in the first case and the outbreak of a purpuric rash without constitutional disturbance in the second. The glandular swellings in the latter, though not previously noticed by the mother, were very evident when the patient was first seen, so that, even if they had not existed from the first, at any rate they occurred at an early stage of the disease. It is to be noted that the onset of purpura in the first case was prodromal to a rapidly fatal termination, only 16 days elapsing between its occurrence and death, while the second, in which, as already stated, the purpura was present from the beginning, was of only one month's duration. In the latter case the marked cardiac dilatation was a prominent feature.

The blood in both instances showed a remarkable diminution in the number of polymorphonuclear cells, with a corresponding increase in the mononuclear elements, which at one time amounted to 97·2 and 98·4 per cent. of the total leucocytes in the two cases respectively. Of these the majority consisted of large lymphocytes; in only one count during the earlier stages of Case 1 did the small variety seem to preponderate, while towards the end of Case 1 and throughout the course of Case 2 the excess of the larger form was very marked. Of the other leucocytes, a few eosinophiles and myelocytes were found in both, and an occasional basophile in the second. This lymphocytic excess, it will be observed, occurred without any great increase in the total number of white cells, the leucocytosis in neither instance at any time exceeding 25,000 per cubic millimetre. The red cells in both cases showed a decided decrease towards the end with the presence of a small number of normoblasts, and degenerative changes were exemplified, in Case 1 at all events, by polychromatophilia. The colour indices throughout were only slightly below 1.

Clinically the signs were consistent with a diagnosis of acute lymphatic leukæmia, early involvement of the lymphatic glands generally, enlargement of the spleen and liver, a progressive anæmia and cachexia, and a tendency to hæmorrhages (very marked in Case 2) followed by an early death, while the markedly increased proportion of lymphocytes in the blood, in spite of the fact that at no time was the leucocytosis of any unusual extent, further completes the picture.

Cases of acute lymphatic leukæmia without marked leucocytic increase have been described, such as that by Cabot,[2] in which the leucocytes fell as the result of sepsis from 40,000 to 471 on the day of death; that by F. Taylor[3] of a boy, aged ten years, whose white cells numbered 15,000 when first seen, but with an increasing lymphocytosis amounted subsequently to 50,000; one by Gilbert and Weil,[4] in which all the leucocytes were lymphocytes and the total numbers varied between 22,010 and 46,400; and two by McCrae,[5] one of a boy, aged three years, who at the first count had 26,000 leucocytes, of which 86·5 per cent. were lymphocytes (45 large and 41·5 small) and subsequently 60,800 with 99·2 per cent. of lymphocytes, the small variety amounting to 96·6 per cent.; the other of a man, aged 20 years, whose leucocyte count was 12,000, the percentage of the total lymphocytes being 94·2 and that of the small kind 93·3. Furthermore, Hutchison[6] states that "it must be admitted that cases of true lymphatic leukæmia do occur in which, at one stage of the process at least, there is no *absolute* increase of the total leucocytes, but in such cases there is notwithstanding a marked absolute increase of lymphocytes, whilst the normal total count is due to a great reduction of the polynuclear forms."

A consideration of the disease from a general standpoint leads to the conclusion that lymphatic leukæmia, or more correctly speaking lymphæmia or lymphocythæmia, is a condition presenting itself in many different forms. The differences met with in these cases are so various that at first it appears that one would be almost justified in asserting that every case is atypical. In spite, however, of the diverse appearances shown by this disease we can divide it into two distinct classes—namely, acute and chronic—and furthermore we can subdivide these two into several types with which are associated certain more or less definite characteristics. In the *chronic* cases, which are decidedly less common than the acute, we have two constant features: (1) there is always a general glandular enlargement; and (2) there is always an extreme leucocytosis—i.e., one approaching 100,000 per cubic millimetre and frequently exceeding that number. The majority of the white cells are lymphocytes (from 85 to 99 per cent) and in these chronic cases the small lymphocytes generally, but not always, predominate. Thus, in a chronic case observed by one of us recently there were 138,000 white cells per cubic millimetre, of which 91·2 per cent. were large lymphocytes and 1·8 per cent. were small.

In the *acute* cases, on the other hand, there may be a general enlargement of the lymph glands or there may not. Cases without glandular enlargement have been described by Reed,[7] Houston,[8] Donovan,[9] Dudgeon,[10] and others. Secondly, the leucocytosis may be extreme or of only a very moderate extent, the total number of white cells not exceeding that frequently seen in an inflammatory leucocytosis. And in the third place, such leucocytosis, whether of a marked or of a moderate grade, may be both sides of the heart there were small quantities of pale watery blood; there were no clots. The heart muscle was pale and flabby, with well-marked tabby-cat striation on the musculi papillares. The right ventricle was moderately dilated. The valves were normal. The mucous membrane of the stomach was coated with tenacious mucus but otherwise the stomach wall appeared normal. The small intestine contained a considerable amount of rather thick bile-stained mucus. The mucous membrane was reddened, especially the edges of the valvulæ conniventes. In the large intestine the mucous membrane was reddened in patches The opening of the appendix into the cæcum was plugged with a small mass of inspissated fæcal matter. The wall of the appendix was in a state of catarrhal inflammation, the proximal half of the appendix being distended with very foul-smelling mucus. The mesenteric glands were slightly enlarged and red. The liver weighed 26 ounces and was very pale in colour. The gall-bladder was distended with dark-coloured bile. The spleen weighed five ounces and was of firm consistence. The kidneys were large, each weighing three and a half ounces; the cortices were not enlarged and the capsules stripped easily. The connective tissue throughout the body was decidedly œdematous. The blood was pale and watery and its coagulability was considerably diminished. Films were made from the bone marrow of a rib. The cells showed a considerable amount of degeneration, many of them staining badly and being difficult to identify. The proportion of non-granular to granular cells appeared to be normal. Nucleated red cells were fairly, but not excessively, numerous, the majority of them being megaloblasts. Of the non-nucleated red cells many were macrocytes. Corpuscle-carrying cells were not present.

This case presents many points suggestive of pernicious anæmia, though the occurrence of this disease so early in life is very unusual, for out of 240 cases collected by Ehrlich only one, or 0·4 per cent, occurred below the age of ten years. The patient was intensely anæmic and during the 14 months that the blood was under observation the red corpuscles were above 2,000,000 for only one period of five months and towards the end they showed considerable variations in size and shape. Nucleated red cells were present in small numbers and in the last count one definite megaloblast was seen. As in pernicious anæmia, rapid changes in the quality of the blood and in the general condition of the patient were marked features. On two occasions the number of erythrocytes fell considerably below 1,000,000 and in the last count of all to 774,000. On the two earlier occasions the numbers were doubled in such short periods as 11 and 15 days, the general condition at the same time noticeably improving after the patient had seemed to be in a very bad way. The hæmoglobin value throughout was high, the average of all the estimations being 1·043. The leucocyte count, on the whole, was low and showed no correspondence with the number of red corpuscles, the highest number, 9200, being found at one of the periods of most marked diminution in the red cells.

An alternative diagnosis which was at one time put forward was that of splenic anæmia, but the spleen was never at any time very large and frequently it could not be felt at all. In splenic anæmia, also, the red corpuscles very rarely show the same marked diminution as in pernicious anæmia and the poikilocytosis is much less marked. Erythroblasts are rare and when present are of normal size and above all the colour index is low. The leucocytes are diminished in number with a slight relative increase in the lymphocytes, and basophiles are very scanty. Taken altogether the blood of this case conforms much more closely to the type of pernicious than to that of splenic anæmia.

The child was shown at a meeting of the Society for the Study of Disease in Children on Oct. 20th, 1905, when it was suggested that the anæmia was due to abdominal tuberculosis, but the necropsy showed no sign of tubercle anywhere.

It is possible that the anæmia supervened upon the chronic gastro-enteritis, and if this be so is it to be considered as merely of a secondary nature? It seems to us that the blood changes were too severe to be accounted for in this way, and for the reasons given above we incline to the belief that the case was one of primary anæmia presenting many characteristics of the pernicious type.

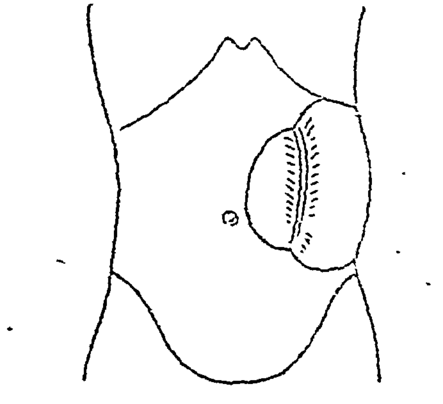
A CONTRIBUTION TO THE PLASTIC SURGERY OF THE RENAL PELVIS.

BY J. W. THOMSON WALKER, M.B. EDIN., F.R.C.S. ENG.,
HUNTERIAN PROFESSOR, ROYAL COLLEGE OF SURGEONS OF ENGLAND; ASSISTANT SURGEON TO THE NORTH-WEST LONDON HOSPITAL AND TO ST. PETER'S HOSPITAL FOR STONE AND OTHER URINARY DISEASES.

CONSERVATISM in renal surgery has succeeded a somewhat prodigal tendency in regard to the renal tissue. This is partly the result of increased experience in the surgery of renal disease but above all to a wider knowledge of the pathology and of the recuperative power of the renal tissue after apparently irreparable damage. Plastic operations upon the ureter and the kidney pelvis are performed with greater frequency with the object of saving the kidney, even if it be damaged. The plastic surgery of the renal pelvis has not yet emerged from the earlier stages of its development and I have therefore ventured to give publicity to the following case, which appears to me to possess some points of interest.

The patient, an active young woman accustomed to the muscular exertion of massaging patients, was under the care of Dr. H. Stanley of St. Leonards and Dr. A. M. Ross Sinclair, and was referred to me on account of a moveable tumour on the left side of the abdomen. She related the following history. Seven months before I saw her she had a sudden attack of pain in the left side of the abdomen and indicated a spot above, and to the left of, the umbilicus a little below the margin of the ribs (anterior renal pain region). The pain was severe and shooting through to the back at the angle of the last rib and the erector spinæ muscle and caused sickness. She stated that just before the pain came on she had carried a heavy box downstairs. The pain was relieved by rest in bed and she remained perfectly well for about three months, when she had an attack of influenza and the same pain returned. This was followed by another attack four months later and the last attack came on four days before I saw her. These attacks of pain were all similar in their course. The first attack had some apparent connexion with lifting a heavy weight, the second had no such preliminary exertion, and the third attack came on at night when the patient was in bed. The pain always commenced in front and passed through to the back. It did not track along the ureter. The kidney region was tender during and after the last two attacks. There were no increased frequency of micturition and no change in the urine during or after the attacks. Dr. Stanley discovered a tumour in the left loin. This did not increase in size nor was there any history of its sudden disappearance.

FIG. 1.



On examining the abdomen the left side was seen to be more prominent than the right and was firmer and more resistant. There was some bulging at the side of the left loin with the patient lying on the back, but none posteriorly. On palpation a large smooth mass of the size of a child's examined. No neuritis. No tubercles of the choroid." A blood count on Oct. 4th showed 1,200,000 red cells and 6400 leucocytes to the cubic millimetre and hæmoglobin 30 per cent.

As the child was losing weight she was admitted into the hospital on Oct. 10th. All the mucous membranes were blanched and she was very pale. The temperature was 103·6° F. and the pulse-rate was 160 and of good quality. The tongue was very furred. Nothing beyond the hæmic bruit was found in the chest but the abdomen was very distended and the spleen could be just felt. The temperature fell to normal in two days but rose irregularly to about 100° for another fortnight, after which it settled down. The pulse also became slower and averaged 100 beats a minute. The blood a week after admission showed only 816,000 red cells and 3400 white to the cubic millimetre, with hæmoglobin 20 per cent., but 11 days later it had improved to 1,695,000 erythrocytes and 6800 leucocytes, with hæmoglobin 42 per cent. Vomiting frequently occurred in spite of all treatment and proved unconnected with the administration of arsenic which was tried, as it did not cease when iron was substituted for a time or increase when the arsenic was resumed. At the end of a six weeks' stay in hospital she was slightly improved and had gained 2¼ pounds, her weight then being 29¾ pounds. She was sent away to Brighton on Nov. 21st but the vomiting became worse and on Dec. 28th she was readmitted, having lost three-quarters of a pound in weight. The abdomen was still distended but there was no evidence of fluid and the spleen could not then be felt. The blood count showed only a slight inferiority to that made on Oct. 29th. The temperature was unsettled, rising quite irregularly at intervals, and occasionally reaching 103°. No cause was found for these rises and they apparently did not cause the patient any inconvenience. A seven weeks' course of hæmatogen, iron, and arsenic brought about some improvement and an increase in weight of nearly 3 pounds. The blood on Feb. 21st, 1905, showed 3,760,000 red cells and 8600 white per cubic millimetre and hæmoglobin 72 per cent.

TABLE III.—GIVING DETAILS OF THE BLOOD EXAMINATION IN CASE 3.

Date.	Red cells per c.mm.	White cells per c.mm.	Hæmoglobin per cent.	Polymorpho-nuclears per cent.	Small lympho-cytes per cent.	Large lympho-cytes per cent.	Large mono-nuclears per cent.	Transitionals per cent.	Eosinophiles per cent.	Myelocytes per cent.	Basophiles per cent.	Nucleated red cells per 100 leucocytes.	Remarks.

Average colour index = 1·043.

The patient was sent home but three weeks later returned with increased vomiting and was readmitted on April 14th. The general condition was much the same but the blood had deteriorated to 2,048,000 red cells and 7500 white per cubic millimetre; hæmoglobin 32 per cent. The temperature continued very irregular and the vomiting persisted at intervals in spite of treatment. In June the spleen was palpable again, two inches below the ribs, and the blood elements had further slightly diminished in number, though the colour index had improved and the weight had risen to 31 pounds 10 ounces. As it was thought that she was not doing very well in hospital she was sent home and kept under observation as an out-patient, being sent again to Brighton a little later. After she had been there for a few weeks her mother was telegraphed for as the child was very ill and the vomiting was severe and brought her straight back to the Evelina Hospital. The patient was a good deal collapsed after the journey and intensely anæmic. Her lips were bluish-white in colour and the hands and ears were of a dead waxy appearance. She was admitted again (Sept. 15th, 1905) and the anæmia was found to be of such an extreme grade that there were only 827,500 erythrocytes to the cubic millimetre, the hæmoglobin being 15 per cent.; the leucocytes, on the other hand, were abundant, numbering 9200. Her condition improved, so that by Oct. 6th the red corpuscles and percentage of hæmoglobin were nearly doubled. The patient was bright and cheerful in herself but was frequently very sick without any feeling of nausea. The vomiting occurred quite suddenly and was generally preceded by a cough. The spleen was not palpable but the lower edge of the liver could be just felt. Both ears were discharging. The bowels, as was generally the case, required aperients. The urine was normal. The vomiting was intractable though for a time it seemed better after lavage of the stomach, a proceeding which the child greatly resented. Towards the end of October the red cells had again begun to diminish in number so she was once more sent home. She weighed 29½ pounds. During November the vomiting was rather less frequent but she became more anæmic and dropped to 28¼ pounds in weight. On Dec. 1st she was much worse and very lethargic and was admitted for the last time. The face and lips were almost white; the eyelids were puffy, and the hands and feet were œdematous. The respirations were laboured and 30 to the minute, the pulse was 104, and the temperature ranged from 101·4° to 102°. The blood count showed only 774,000 red cells and 4370 white per cubic millimetre and hæmoglobin 18 per cent. (See Table III.) The temperature dropped to normal but the child died on Dec. 5th, 1905, having complained of pain in the abdomen and back during the previous day.

Necropsy.—At the post-mortem examination the body was found to be fairly well nourished. Rigor mortis was slight and post-mortem staining was not present. The muscles were brownish-red and the fat was a deep yellow. The lungs were very œdematous. Both pleural cavities contained a large quantity of clear fluid. There were some recent adhesions about the base of the left lung. The peribronchial glands were large and pigmented. The pericardium contained nearly three ounces of cle little difficulty it was brought out on to the loin and this condition was found. The kidney was attached to a large bladder-like cyst which was recognised as an enormously distended pelvis. The kidney itself was dilated to a moderate degree. The whole mass, cyst and kidney, was of about the size of a child's head. The ureter was picked up below the mass and traced upwards. It was small and showed no signs of dilatation or thickening. The upper end lay upon the surface of the cyst and was firmly bound down to it by adhesions for about one and a half inches. (Fig. 2.) The renal pedicle was long and allowed the mass to lie upon the loin without putting any strain on the vessels, so that the necessary manipulations of a plastic operation were carried out in comfort. The ureter was dissected up off the surface of the cyst until its junction became perpendicular (Fig. 3) and a longitudinal incision was then made from the point of union along the posterior surface of the ballooned pelvis almost to the margin of the kidney hilum. The cyst collapsed and allowed a careful survey of the interior of the dilated pelvis and kidney; a bougie was inserted into the upper end of the ureter and passed readily down to the bladder. There was no narrowing at the point of junction between ureter and pelvis. The incision in the wall of the pelvis was continued into the ureter by slitting this tube for about a quarter of an inch. A large triangular portion of the posterior wall of the renal pelvis was now cut away, the base of the triangle lying about a quarter of an inch from the margin of the kidney hilum. (Fig. 4.) An incision was made in the convex border of the kidney about its mid point, and a long pair of artery forceps was pushed through this into the cavity of the pelvis and the conical point inserted into the upper end of the ureter. (Fig. 5.) Over this the margins of the wound of the pelvis were then brought together, and a series of interrupted sutures of fine silk was inserted. (Fig. 6.) In this way the lateral angles of the triangle met about one-third of the distance from the renal end of the wound. The kidney itself was bent pole towards pole so that these angles might be approximated, but there was no tension or kinking of the organ, and when all was finished the bend in the middle of the kidney had almost disappeared. The leathery wall of the pelvis did not admit of the application of Lembert or other special sutures, and a series of closely set interrupted stitches passing through the whole thickness of the pelvic wall was used. With the wound closed and the kidney held in the position it would eventually occupy the pelvis was now reduced to a hollow cone which passed without constriction or angle into the ureter. An incision was now made through the fibrous capsule of the kidney in the form of an ellipse around the wound in its convex border and further incisions from this along the convex border to each pole. The capsule of the kidney was then stripped from the anterior and posterior surfaces of the organ, leaving a margin of about three-quarters of an inch around the wound undisturbed. The capsule from the anterior surface was clipped away at the margin of the hilum, but that from the posterior surface, still attached along the posterior margin of the hilum, was turned over so as to cover the wound in the pelvis, and a few retaining stitches were placed along the edges. (Fig. 7.) Four stout strands of catgut were passed through the kidney substance so as to bring the edges of the kidney wound together, being so placed that the points of entrance and exit were within the surface area undenuded of capsule. These were tied and the ends left long. The kidney was then returned to the abdomen. In turn each of the ends of catgut were threaded on curved needles and brought through the muscles at the upper and lower edges of the lumbar wound and tied so that they formed a part of the series of muscle sutures. Thus each catgut suture passed through the kidney substance uniting the edges of the kidney wound and then one end passed through the muscles of the upper margin of the lumbar wound, while the other end passed through the muscles of the lower part of the wound and the ends were again knotted. The muscle layers were then united by catgut sutures and the skin wound was closed, leaving a rubber drain down to the posterior surface of the kidney. The drain was removed in 36 hours as there was no trace of urine on the dressings. Healing was aseptic and the recovery from the operation was uneventful.

On examining the patient eight months after the operation the kidney was found in the position it had been given at the operation. It was small and moved with the respiratory movements. There was no pain or other urinary symptom and no tenderness was experienced on handling the kidney. The patient was unwilling to submit to a further separation of the urines so that I had to forego the analysis of the secretion of the restored kidney.

One or two points merit brief notice. The condition was undoubtedly primarily a moveable kidney in which the ureter had become kinked and fixed to the surface of the pelvis by adhesions. The mechanism of this is not difficult to reconstruct. The moveable kidney swings around its vascular pedicle so that the hilum ever faces the vascular attachment, being directed upwards and to the middle line or directly upwards. The ureter thus acts as a drag upon the swing. The wonder is rather that kinking so seldom occurs and that the kink is not more often perpetuated by the formation of adhesions. Probably the ureter escapes from the fact that the swing is seldom a direct one, like that o pendulum, and a certain amount of rolling over is added which to some extent releases the ureteral bend. If the pelvis has once become distended the bent ureter lying upon its surface becomes fixed there by adhesions and further distension increases the obstruction to the outlet by pressing upon the tube. In this case there was certainly no true stricture formation at the upper end of the ureter such as has been found in some similar cases, nor was there any vascular cord over which the ureter was bent.

In regard to the plastic operation upon the kidney pelvis but little need be said. So far as I am aware, the method of excision of a large triangular portion of the kidney pelvis in order to reduce its capacity has not been previously employed.[1] The covering of the wound with kidney capsule is an additional novelty. Further, the method of fixing the kidney in this case is one which seems to me to have something in its favour. It is a combination of the decortication with the non-decortication methods which I am inclined to believe has some of the advantages of both. The object of leaving an area of renal capsule through which the sutures enter and emerge is the prevention of cutting out of the suture. Again and again I have met with the difficulty of the cutting of sutures through a friable decorticated renal substance, but since adopting this method of leaving an island of capsule I have had no further trouble on this account. The stripping of the rest of the capsule insures all the advantages which are claimed for the methods of decortication. I employed at one time a method by which the capsule was stripped forwards and backwards from a median vertical incision along the convex border of the kidney. By rolling these pads of capsule up along the anterior and posterior margins of the hilum a roll was obtained through which sutures might be passed and fixed to the upper and lower margins of the lumbar wound. This method, or something similar, has, I find, been used by Mr. W. H. A. Jacobson, who did not, however, strip the capsule from more than half the surfaces of the kidney. *I have experienced* certain disadvantages with this procedure. The sutures if drawn tight will project the denuded kidney into the lumbar wound and it is sometimes a matter of difficulty to find a sufficient muscular covering for the organ. This implantation of the kidney among the lumbar muscles appeared to me to have the advantage of securely fixing the organ in place, but the weakening of the abdominal wall was considerable and was not, I thought, sufficiently compensated for by the increased surety of fixation. But another consideration decided me to abandon the method. It is, I believe, of the utmost importance to explore these kidneys by incision, for, in some of them at least, the symptoms result rather from some renal disease than from the actual mobility of the organ. Such being the case, an incision and exploration of the organ are a safeguard against the serious fault of overlooking an important disease while attending to what in such a case is a minor trouble. An incision in a decorticated kidney, as I have said, is a difficult wound to close on account of the friability of the tissues denuded of capsule. For these reasons I have abandoned the method and prefer that which I have described.

It is an important point that the catgut sutures which close head could be felt in the left lumbar region. The mass had smooth rounded surfaces and no edges or notch. It was oval in shape and appeared to consist of two portions marked off from each other by a vertical groove. (Fig. 1.) With the patient lying on the back it did not quite reach the umbilicus and the lower limit was just above the iliac crest. The mass occupied the renal area and could be readily palpated between the hands placed at the costal angle and on the front of the abdomen. It moved freely with respiration. It could be pushed in all directions. When pushed downwards into the iliac fossa the fingers could be slipped above it between the ribs and the mass. On pushing it up under the ribs a bulging of the epigastric space took place. The mass could be readily pushed across the middle line until its right limit was midway between the umbilicus and the right side of the abdomen. In all its movements it appeared to swing round a pedicle fixed above the umbilicus. It could not be forced down into the pelvis. On lying upon the right side the mass fell away from the left loin towards the right side. There were absolute dulness on percussion over the portion of the swelling to the left of the groove and comparative dulness over that part to the right of the groove. There was no tenderness or aching. The mass was firm but not hard. No fluctuation could be obtained. The temperature was normal. The urine contained some phosphates, a trace of albumin, and there were a few pus cells and granular and hyaline tube casts. With the cystoscope the bladder was healthy and both ureteral openings were normal. No efflux could be seen from the left side. With a Luys separator a small quantity of urine was obtained from the left side and this contained a trace of albumin, pus, and epithelial cells, and a few granular and hyaline casts. The right urine showed no albumin but a few casts were present. The diagnosis of moveable kidney with hydronephrosis was made.

---

[1] In a recent paper (Bulletin of the Johns Hopkins Hospital, June, 1906) Kelly states that he has twice employed "plication in hydronephrotic renal pelvis." The method has already been described by Israel. It is open to the objection that if any permanent kinking or stricture exists it remains untreated, and it is a difficult matter, without opening the pelvis and actually probing the ureter, to say whether or not there is some narrowing of the uretero-pelvic junction or an oblique insert of this tube.

Triangular flap of cyst wall thrown down, showing the interior of dilated kidney. Fig. 5. Portion of cyst wall removed and forceps in position. Fig. 6. Edges of wound united. Dotted lines show incisions through fibrous capsule. Fig. 7. Capsule stripped and stitched over wound. Kidney sutures in position.

The kidney was exposed by a moderate-sized oblique lumbar incision and presented in the wound; with has a marked effect on leucocytosis. A very full account is given of drugs that act on certain nerve cells, such as coniine, nicotine, and their allies. In this connexion the diagrams and work of Langley are introduced with useful effect to help to lighten the path of the struggling pharmacologist, whose knowledge of physiology and the complexities of the ganglionic nervous arrangements may be somewhat rusty. The fruitful subject of drugs that produce convulsions, whether they are discharged from the cerebrum, bulb, or cord, is also treated mainly from the point of view of the pharmacologist.

The vegetable hypnotics, represented by opium and its derivates and the local anæsthetics, are fully and intelligently treated, and bring the student to the details of the group of diuretics, and of cardiac tonics, when, by a sudden transition, we arrive at Chapter XII. on certain drugs which excite sensory nerve endings, such as aconite, veratrine, and stavesacre. Ergot and drugs altering the calibre of the bloodvessels take up two more chapters, and between these chapters and the chapter on the coal-tar or aromatic group (including antipyretics, antiseptics, and disinfectants) is the chapter on cinchona bark. Purgatives, cholagogues, astringents, and simple bitters follow, and then we proceed to a full account of the drugs affecting respiration. Next comes a consideration of essential oils and drugs acting on the skin. This leads up to the theory of ions, and thus onwards to the action of various bases, acids and alkalies, the group of the halogens, and the heavy metals, such as arsenic, antimony, mercury, and iron. Chapter XXX. (pp. 402–11) deals with anthelmintics and drugs used to kill parasites; and then the student finds himself studying emollients, demulcents, sweetening and colouring agents, to wind up with information about ferments, cod-liver oil, vegetable toxins, internal secretions, serum therapy, and antagonism.

We have briefly enumerated the subjects treated in their order, but it should be noted that at the end of each group or chapter there is added a materia medica dealing with the "preparations" of the drugs the action of which is discussed. Many tracings, well printed, afford testimony to the value of the graphic method as applied to pharmacology, while a considerable number of excellent schemata such as teachers frequently use will be found helpful. The work is a compact review of all the leading facts and theories in pharmacology which will be welcomed by teachers of this subject. Perhaps the student will view the additional knowledge from a different standpoint, but the old traditions of materia medica in its wide sense are gradually being replaced by accurate knowledge of the actions of drugs, and as the student has to learn the newer knowledge, the sooner the old teaching is given up the better, so that space may be found in his mental pigeon-holes for facts of greater value.

Text book of Physiology for Medical Students and Physicians. By W. H. HOWELL, M.D. Illustrated. London and Philadelphia: W. B. Saunders and Co. 1905. Pp. 905. Price 18s. net.

PHYSIOLOGY is a continually growing science and nothing shows it more than the steady output of new text-books on this subject or the steady flow of new editions of what are regarded as standard works. The book before us, by the eminent professor of physiology in the Johns Hopkins University, Baltimore, is, we think, a great improvement on the "American Text-book of Physiology" edited by the same author. It is divided into eight sections which deal successively with muscle and nerve, the central nervous system, the special senses, blood and lymph, circulation, respiration, digestion and secretion, heat production and regulation, and reproduction. Of general physiology in the ordinary sense there is practically none, nor is it necessary, for the medical student as a rule has learned the broad principles in his biological course. Where all is so good and so tersely put it is difficult to say which of the eight sections is the best, but perhaps those on the special senses and the nervous system show the author at his finest. The subjects are concisely treated, yet with a lucidity that makes reading a pleasure. A small yet sufficient number of references to literature are given for the sake of those who may wish to follow any particular subject more in detail, while occasional references to works of historical importance are inserted. An appendix dealing with proteids and their classification and diffusion and osmosis closes the work and brings the text to nearly 900 pages. The number of illustrations is 272 and some of them are full-page plates in colour taken from standard works.

This is one of the best recent text-books on physiology, and we warmly commend it to the attention of medical students who desire to obtain by reading a general all-round, yet concise, survey of the scope, facts, theories, and speculations that make up its subject matter. Moreover, the physician also will find much in its pages that will throw new light on many problems of disease.

Principia Therapeutica. By HARRINGTON SAINSBURY, M.D. Lond., F.R.C.P. Lond., Physician to the Royal Free Hospital and to the City Hospital for Diseases of the Chest. London: Methuen and Co. Pp. xi.–244. Price 7s. 6d. net.

IN his prologue Dr. Sainsbury reminds us that the master thinker, Plato, said that "an unexamined life is not worth living." The author would apply the same criticism to medical practice; and for this reason, and because we are in peril of being engulfed in the flood of new remedies, he here sets down certain considerations in the hope that they may prove of service "to those who have undertaken to navigate the ship of health." His book is one of general principles and as such is valuable, while he justly points out that "details without guiding principles yield but a busy foolishness." The book is the work of a scholarly mind and makes most pleasant and instructive reading; it is true, however, that it is written chiefly for the man of leisure, while the busy worker will feel that much that is so true and so well said in this book might have been put into a very much smaller compass. Perhaps it might, but as a literary performance the present shape of the volume is justified. The book is divided into a Prologue, 12 chapters, and an Epilogue. Of the 12 chapters, the first is written in the form of a dialogue between a physician and a pathologist, the scene being in a dead-house. The second and third chapters deal with curative and preventive medicine, the fourth chapter is headed "Primum Non Nocere;" and the fifth "Secundo Prodesse." In the sixth chapter the combining of remedies, therapeutic complexity, reinforcement, and antagonism are discussed. In the remaining chapters the prescription, dietetics, habit, and the order of treatment are considered. The final chapter is headed "Imponderabilia" and has for its motto, "Non pane solo vivet homo"—a motto which may be regarded as a good sub-title for the whole book. We will close this brief notice of a most interesting volume by quoting two characteristic passages in illustration of Dr. Sainsbury's turn of mind. In writing of death he says: "Forbidding enough 'his images and storied aspects,' whilst we contend with him for the mastery, but his victory assured and accepted there follows peace, and for the wounds which he has himself inflicted, it is his custom to administer an unfailing opiate—in a drowsiness we take our departure." He writes that "we should bring to the bedside a great hopefulness, a determined optimism, but if, thus armed, the futility of the strife is irresistibly borne in upon us, then we should put aside our remedia as the renal wound serve also to sling the kidney, for the insertion of additional sutures is thus avoided. The fixed kidney in this, as in most of these methods, is in an unnatural position, lying more obliquely and much lower than in its normal state. This is, however, in my experience no disadvantage, for I have not seen any resulting sign of obstruction to the ureter in the cases in which the kidney was fixed in this position.

Queen Anne-street, W.

Reviews and Notices of Books.

Manual of Medicine. By THOMAS KIRKPATRICK MONRO, M.A., M.D Glasg. Second edition. University Series. London: Baillière, Tindall, and Cox. 1906. Pp. 1022. Price 15*s.* net.

ON the appearance of the first edition of this excellent manual of medicine we had the pleasure of reviewing it very favourably. The second edition is now before us and has been brought quite up to date by the author. Fresh articles have been written on *tropical splenomegaly, trypanosomiasis,* and piroplasmosis; additional illustrations have been introduced and one figure showing the cortical centres on the lateral aspect of the hemisphere has been re-drawn, so as to represent the most recently accepted teaching.

The volume opens with the subjects of fever and of the specific infectious fevers. In writing of typhoid fever we do not find any mention of the advisability of giving urotropine as a measure of preventing infection by the urine. The researches of Dr. P. Horton Smith might with advantage be alluded to in a future edition. The section on relapsing fever is well up to date, the investigations of Dr. Dutton and Dr. Todd receiving due mention. Lobar pneumonia is, of course, placed amongst the infectious fevers. The author, in the treatment of this affection, we are sorry to see, does not mention antimony. In writing of tuberculosis he evidently does not agree (and here he is in consonance with most authorities) with the dictum of Koch that there is little or no danger from tuberculous cattle. The section on this disease is very complete. The treatment advised in cholera is not altogether satisfactory. For instance, the author recommends the diarrhœa to be checked by astringents, whereas there can be little doubt, we believe, that the treatment by purgatives is by far the best, and, indeed, this was recognised a few years ago by the Royal College of Physicians of London. No mention is made of the late Sir George Johnson's lucid theory of collapse. Yellow fever is handled in a very satisfactory manner and the importance of the rôle played by the mosquito is fully set forth. Hamilton Wright's investigations on beri-beri receive their due appreciation and the latest researches on yaws are set forth. The author's successful attempt to keep his manual up to date is well exemplified by his treatment of the subject of tropical splenomegaly, wherein the recent views of Major W. B. Leishman, R.A.M.C., Major C. Donovan, I.M.S., Captain L. Rogers, I.M.S., and Lieutenant S. R. Christophers, I.M.S., are all set forth. In the account of trypanosomiasis and piroplasmosis the student will find all the most recent researches detailed.

Section II. is devoted to constitutional diseases. The theories concerning gout are detailed, special attention being paid to the researches of the late Sir William Roberts. In the treatment of osteo-arthritis the administration of guaiacol carbonate might perhaps have been more strongly recommended. The chapter on diabetes is excellent and nothing of importance is therein omitted.

In Section III. we find an account of the diseases of the circulatory system. We cannot congratulate the author on the diagrams showing the relation of the valves but the illustration of the relations of the heart and great vessels to the lungs and thoracic walls is excellent. The varieties of the pulse are very lucidly set forth. In that dread disease, ulcerative endocarditis, antistreptococcic serum is rightly advised. In the section on the various valvular lesions the author, as regards prognosis, considers that mitral incompetence is the least dangerous; next comes aortic stenosis, then mitral stenosis (probably); and, finally, aortic incompetence, thus not completely agreeing with the views of Sir William Broadbent

Passing on to the subject of aortic aneurysm, we are glad to see that the author draws attention to the method of treatment by the hypodermic injection of a 2 per cent. sterilised solution of gelatin. He, however, advises the gelatin solution to be given by the rectum in view of the fact that many cases of tetanus have followed this plan of treatment. The account of the different varieties of corpuscles of the blood in various diseases is succinctly written and should not cause in the mind of the reader any confusion, which cannot invariably be stated concerning such accounts. The different diseases of the blood are also described in a very luminous manner, the only affection that might be more fully set forth being scurvy, as there is no mention here of any of the theories that have been put forth to explain it, such as those of the late Dr. S. H. Ralfe or of Sir A. E. Wright. The sections devoted to the respiratory, digestive, and renal systems next follow and here the article on Abscess of the Liver is not quite up to date as no mention is made of the sub-hepatic abscess of Cantlie.

The section on diseases of the nervous system is the best in the volume. There is an excellent diagram representing the sensory and motor neurons. The whole subject—one that generally is extremely difficult to the student—is so well and lucidly set forth that it is a pleasure to read it. The diagrams employed are excellent and the descriptions of the various diseases leave little or nothing to be desired. The author is to be congratulated heartily on this section of the work. Finally, the volume ends with an account of the diseases of the skin, of the various intoxications, and of the diseases due to parasites. In the chapter on sunstroke we note that no mention is made of the actinic theory, an omission of some importance with respect to the successful prophylaxis founded on this theory.

A Manual of Pharmacology. By WALTER E. DIXON, M.D. Lond. Illustrated; 86 figures in the text. London: Edward Arnold. 1906. Pp. 451. *Price* 15*s.* net.

THE object of this manual is to give the student a simple account of the science, albeit an experimental science, of pharmacology; the work is not a text-book on materia medica, while the introduction of therapeutics is only to serve to illustrate the pharmacology. The art of therapeutics can only be dealt with properly at the bedside, and the author thinks that the student should not be burdened by committing to memory the composition of various pharmaceutical preparations. We agree with him here, for the modern student is already overtaxed by an unnecessary amount of such futile labour.

After some general statements the author deals with alcohol and its action, and he considers that the direct evidence is almost overwhelming in support of the theory of Schmiedeberg—that this drug does not exert any direct stimulant action on the central nervous system but that on the contrary it depresses from the beginning. Anæsthetics, narcotics, and hypnotics are next dealt with, and some of the actions of these drugs are illustrated by excellent tracings. A more or less specific group of drugs which act on nerve endings is considered, including those which excite (colchicine, pilocarpine, muscarine, and so on) or depress the activity of nerve endings (belladonna, stramonium, and hyoscyamus). Colchicine, in addition, entirely sensible all that the author says of the value of fresh air in towns, of the physique of boys and girls, of clothing, and of exercise. Mr. Cantlie feels strongly on the subject of infant feeding and is somewhat hard upon the monthly nurse who recommends that the mothers should give up feeding their children. It is always unsound to attribute motives in the course of an argument, and we think that Mr. Cantlie goes a little too far in suggesting that our nation is being hurled to destruction through selfishness on the nurse's part and the desire to be free from the *mother's interference*. We are glad, however, to see the condemnation of the infant's "comforter" (the solid indiarubber teat), though it may be doubted whether it is really the constant cause of adenoids. On the subject of dancing as a mode of exercise Mr. Cantlie desires that we should learn its significance, and as an example he analyses the various figures in the now *neglected* quadrille. With the same intention the author has much to say in favour of gymnastics and gymnasium drill, while the postscript speaks of the physical efficiency of the Volunteers and the importance of developing this force instead of *reducing its numbers*. There can be no doubt of the immense national importance of physical efficiency, and for those who must be approached without circumlocution, without unnecessary detail, and without any assumption by the author that they are *familiar with* physiology or physiological literature Mr. Cantlie's book should be quite serviceable. Well-written prefatory remarks will serve to impress the audience aimed at with the great interests involved in an organised attempt to improve the national physique.

JOURNALS AND MAGAZINES.

The Liverpool Medico-Chirurgical Journal.—With the July issue, as stated in the preface, this journal "is presented under those broader auspices which we feel *convinced* are necessary to its professional success and financial stability." Its editor is Dr. John Hay, assisted by a strong editorial committee with Sir James Barr as chairman. This number runs into 331 pages, of which 308 are practically original matter, derived chiefly from the proceedings of the Liverpool Medical Institution. Medicine, surgery, gynæcology, and pathology, besides special branches, are all represented by valuable contributions. We can only allude to the article by Dr. William Carter on the Use of Small Doses of Potassium Iodide and to that by Mr. John H. Watson on Polycythæmia Vera, with a note on an instrument for estimating the viscosity of the blood (a description of which was published in THE LANCET of July 14th, p. 89), in the medical section; and to those on Intraperitoneal Rupture of the Bladder and on Internal Derangement of the Knee Joint, by Mr. R. W. Murray and Mr. W. Thelwall Thomas respectively among the surgical papers. We have already commented on a new theory of female genital activity, by Dr. W. Blair Bell,[1] in which the uterus is regarded as giving rise to an *important* secretion.

The Medical Chronicle.—In the July number Professor G. A. Wright deals with the Nomenclature and Classification of Diseases of the Joints and proposes a new scheme of arrangement of these conditions, many of which seem as yet too little understood to admit of definite classification. A paper by Dr. David Drummond contains some interesting observations on symptoms met with in cases of heart disease, and a note by Mr. E. D. Telford records a case of Cancrum Oris in which recovery took place after injection of diphtherial antitoxin.

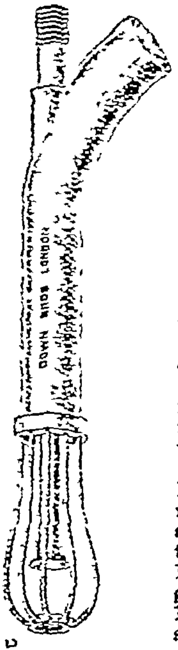
New Inventions.

A TWO-WAY PERITONEAL IRRIGATOR.

IN spite of the weighty and widespread opinion in favour of dry swabbing in purulent peritonitis, as opposed to irrigation with normal saline solution, I am still of opinion that the latter method is the better, provided one can irrigate without forcing infective fluid into non-infected areas. That is practically impossible by the ordinary methods of irrigation. At my instigation Messrs. Down Brothers, Limited, have made the instrument here depicted, which, I think, permits, indeed favours, localised flushing without infecting non-infected areas. The instrument consists of a central delivery tube, made bell shaped at its distal end so as to dissipate the force of the injected fluid. The egg-whisk arrangement, made of strong smooth wire, prevents coils of bowel pressing around the mouth of the exit tube and thus obstructing the outflow of the irrigating fluid and at the same time allows irrigation of the adjacent parts. The exit tube surrounds the delivery tube at its proximal end and the exit area is several times greater than the sectional area of the delivery tube. The exit tube is continued laterally by a stiff rubber tube of sufficient length to reach a receptacle at the side of the table. When this rubber tube is filled with fluid a strong syphon action is obtained. The advantage of this is evident. If by any chance the suction draws intestine between the wires of the "whisk" part gentle nipping of the rubber part will tend to remedy the tendency. The instrument can be taken to pieces for cleaning purposes.



A few weeks after Messrs. Down Brothers had made the instrument for me I was much interested to find that a somewhat similar device had been thought of and put into practical shape by Dr. Joseph A. Blake of New York ("Surgery, Gynæcology, and Obstetrics," May, 1906). I venture to think that the instrument figured here is superior to his and will give even better results than he has obtained. By the use of such an instrument much time, manipulation, and mechanical insult of the peritoneum are saved, thereby lessening shock. There is not the same tendency for the bowel to protrude as with the usual method of irrigation. There is infinitely less danger of carrying infection to uninfected areas. The irrigation may be carried out through a small incision if that be thought desirable. It will indicate, as Dr. Blake points out, the extent of the infection if one watches the condition of the returning fluid as the various peritoneal recesses are successively washed out.

H. M. W. GRAY, M.B. Aberd., F.R.C.S. Edin.

Aberdeen.

FLEECY MATERIAL FOR WET-BANDAGING.

THE Sandown Company of Stanford-street, Nottingham, has sent us a sample of a new kind of bandage which is said to be used extensively by veterinary surgeons for the wet-bandaging of the legs of horses, and the suggestion is made that these bandages might sometimes prove useful in medical or surgical practice. The sample which we have received is of varying thickness. One portion, which is about three and a half feet long and three and three quarter inches wide, consists of a double thickness of a soft fleecy material; the fleecy portion then comes to an end and the bandage is continued for a further distance of about four feet in a material resembling the leg of an ordinary cotton stocking woven circularly, so that it is everywhere smooth, soft, and of double thickness, without any possibility of fraying out at the edge. An extraordinary power of retaining moisture is claimed for this bandage and it is said to have been found beneficial in the treatment of sore throats and sprained joints.

cures, and ranging ourselves upon the side of Death, make easy the couch with such solatia as may offer. He would come as a friend, let us not compel him to hostility, since he must prevail." We welcome this book as the work of a scholar and an erudite physician.

LIBRARY TABLE.

Phlebitis and Thrombosis: the Hunterian Lectures. By WARRINGTON HAWARD, F.R C S. Eng., Consulting Surgeon to St. George's Hospital. London: *Baillière, Tindall, and Cox.* 1906. Pp. 88. Price 5s. net.—In these Hunterian Lectures Mr. Haward gives us an able and scholarly survey of the present position of our knowledge of phlebitis and thrombosis. For some years he has been making and collecting observations relating to thrombosis and he has found that the remoter effects of the disease do not seem to have attracted much attention from surgeons. These collected lectures are especially valuable because the author devotes considerable space to the treatment of the conditions he describes; though his suggestions would be even more valuable to the practitioner if the prescriptions for the various applications recommended were set forth in full. But consideration of the time at his disposal probably dictated the scope which the lecturer laid down for himself. Mr. Haward dwells on the smallness of our knowledge of the vital chemistry and physiology of the blood and remarks that "here is a wide and fertile field for our advancing physiological chemists." The book is illustrated with eight excellent plates.

Traitement des Hémorragies Puerpérales. Par le Docteur G. KEIM, Ancien Interne des Hôpitaux de Paris et des Maternités de l'Hôtel Dieu, Saint-Antoine, et Lariboisière. Paris: Vigot Frères. 1905. Pp. 235. Prix 3 fr. 50c.—As the author truly remarks in his preface, the treatment of the hæmorrhages occurring in connexion with childbed requires a very perfect knowledge of what is to be done and promptitude in carrying out whatever measures the medical man may select. With a view to assisting the latter in coming to a conclusion what to do in such cases, and how to do it, Dr. Keim has collected together in this book the different methods of treating hæmorrhage when it occurs during pregnancy, during labour, or in the puerperium. As a necessary preliminary to the study of the artificial arrest of bleeding the author devotes a chapter to the anatomy of the pregnant uterus, and this is followed by one on the defences of the organism as a whole against hæmorrhage. He next discusses the various medicinal remedies and modes of treatment, and then considers the best methods to pursue in the different forms of hæmorrhage which may be met with. Lastly, he describes the means of treating the various conditions which ensue as a consequence of the loss of large quantities of blood from the body. The book presents within a small compass a considerable amount of information, and should prove of value to students and practitioners acquainted with the French language.

Health Talks about Children: An Appeal for the Child. By JOHN GRIMSHAW, M.D., B S. Lond., D P.H. Cantab. Birkenhead: Brimmell's Printing Works. 1906. Pp. 83 Price 1s. net; postage 2d—The health and lives of infants and young children are so needlessly sacrificed by avoidable mistakes that any additional way of diffusing information must be welcomed Dr. Grimshaw's book is written with the "good intentions of helping mothers to care for their children and of inspiring others to help the mothers," and is dated from the "Dispensary for Children, Conway-street, Birkenhead." The teaching is all very obvious; for instance, he insists that "it cannot be too strongly impressed upon the mother that many of the symptoms and sicknesses of the infant are better treated by careful feeding or by modifications in the food than by drugs. Most children who resist this form of treatment, or that by suitable measures of hygiene, are not amenable to healing by medicine." The book is divided into six chapters, or "Health Talks," as the author designates them, and an appendix which is a valuable part of the book. In the appendix carefully drawn up rules are set forth for the feeding and bringing up of children, and the mother is advised "What to do and what not to do" in terms that should make her avoid many omissions and transgressions. The sixth "talk" is headed "Consider the Child" and is an appeal to the social reformer. Dr. Grimshaw inveighs against the old-fashioned babies' bottle and advises that we should follow the steps of France and certain States of the American Union where the sale of such bottles is illegal. The book is quite a sound collection of approved facts presented in a way which ought to convince the mother and be very helpful to her.

The Care of Children. Practical Hints for Mothers and Nurses at Home and Abroad. By ROBERT J. BLACKHAM, D P.H R C P S. Lond., Captain, R A M.C. Revised and enlarged edition. London: The Scientific Press, Limited. Pp. 84. Price 1s. 6d net.—The author tells us in his preface that many readers of the first edition of this little book suggested that he should prepare an enlarged edition which would appeal to a wider circle of readers than that for which the "Hints" were originally intended. A study of the report of Mr. T. W. N. Barlow, the medical officer of health of Bootle (Liverpool), which was published in 1905, has induced him to comply with the suggestions made to him. Captain Blackham entirely concurs in Mr. Barlow's view that it is by the education of mothers and nurses alone that the dark pall of ignorance can be dispelled, only in this way can the problem of the proper feeding of children, the most important of all questions affecting the well-being of humanity throughout the civilised world, be efficiently dealt with. The book is clearly intended for the mother and the nurse and has been prepared from the points of view both of a medical officer of health and of a family physician. Captain Blackham divides his work into nine chapters as follows: Hints on Food; Hints on Drink and Medicines; Hints on Clothing; Hints on Cleanliness; Hints on Rest and Exercise; Hints on Infectious Diseases; Hints on the Nursery; Hints on Nursery "First Aid"; and Hints on Nursery Cookery. We have examined this little book carefully and find it thoroughly sound. It is a collection of truths and experiences by which, if studied by mothers and nurses, the readers will be assisted to rear healthy children. The author does not pretend that he has discovered anything new but he has given us a most useful collection of truths in regard to children expressed in good English and arranged in a convenient way.

Physical Efficiency. By JAMES CANTLIE, *M.A., M.B. Aberd.,* D P H. R C P. Lond. With a Preface by Sir LAUDER BRUNTON and a Foreword by Sir JAMES CRICHTON-BROWNE London and New York: *G. P. Putnam's Sons.* 1906. Pp. xxviii.-216. Price 3s. 6d.—The author has intended to present a popular review of the deleterious effects of town life upon the population of Britain and to give suggestions for their arrest. The importance of the subject is vouched for by topical and curious quotations from lectures at Exeter Hall and at the Parkes Museum of Hygiene, from *Punch* and other papers, from Shakespeare, and from the English Mr. Winston Churchill. The style is emphatic and picturesque, which means to say that it is well calculated to arrest the attention of persons not in the habit of looking deeply into what they read. We find this malady shall not be subject to any of the disabilities under the penal clauses of the Public Health Act, 1875, or other sanitary Acts. This latter is a wise and, in our view, necessary exception, but we believe that there are still some who see no objection to dealing with pulmonary tuberculosis in the same fashion as it is customary to deal with small-pox. Those who think in this way would have a case of notified pulmonary tuberculosis confined to his home or to a sanatorium until the treatment adopted or the intervention of death should set him free again, but the bulk of public and of professional opinion is against this extreme view. But modified notification, especially in the larger towns, appears to be meeting with a fair measure of success, and where this is the case the fact is doubtless due to the circumstance that the medical officer of health recognises the absolute necessity for caution and discretion in the matter. But in order that notification may meet with genuine success the coöperation of the medical practitioner is essential, and if the profession generally feels that the information which it furnishes to the health officer is being abused, and is leading to unjustifiable hardship to the patient, there must be difficulties in inducing the medical practitioner to notify. We mention this because, as far as we can judge from the material at present available, there is, perhaps in a few isolated cases, a disposition on the part of sanitary authorities to press matters in the same fashion as is necessary in dealing with the highly infectious diseases, such as small-pox and typhus fever. We are glad to see that medical officers of health are recognising the impossibility of such an attitude.

But granted the principle of modified notification of pulmonary tuberculosis, there is still some difference of opinion as to procedure. To notify a case of pulmonary tuberculosis because there is a suspicious dulness at one apex is altogether unjustifiable, there being no danger to the public from such a case. We note, therefore, with pleasure in connexion with the coöperation of the medical practitioner with the health officer, that in the case of Birmingham, where voluntary notification was adopted last year, the medical officer of health (Dr. J. Robertson) has pointed out in his current annual report (after referring to the fact that although a considerable number of cases have been notified among the artisan class comparatively few have been notified from the middle and upper classes) as follows: "It will be recognised, however, that among the middle and upper classes such notifications are not necessary because in the majority of cases the patients already receive the necessary instructions in the way of preventing them from becoming sources of infection to others." Although in a sense this raises a somewhat invidious class distinction and puts a heavy burden, as it were, upon that class which is least able to bear it, the distinction is, we think, a thoroughly logical one. Clearly also Dr. Robertson does not contemplate that cases of pulmonary tuberculosis with no expectoration shall be notified, since in drawing attention to the facilities obtaining at the University of Birmingham for the bacteriological examination of sputum he observes: "From experience elsewhere I think it advisable that such an examination should be made in most of the cases you intend to notify." The desirability of differentiating between cases in which there is expectoration and those in which there is none ought now to be widely recognised. As regards Birmingham, again, we notice with satisfaction that in setting forth the objects which the health committee has in view, when inviting medical practitioners to notify suitable cases of pulmonary tuberculosis, Dr. Robertson places in the forefront the fact that the information obtained will enable the committee to deal with many of the housing conditions which contribute so largely to the causation of the disease, while the state of the workshops and other trade conditions which influence the spread of the disease will also come under notice. In all this Dr. Robertson is exhibiting, we think, a statesmanlike attitude, for if it is possible to direct some of the enthusiasm in favour of a crusade against tuberculosis, which is now abroad in this country, towards the improvement of the housing conditions of the poorer classes, we venture to predict that pulmonary tuberculosis will decline more rapidly than has been the case in England and Wales for very many years past. And with the decline in this disease, through action set in motion against overcrowding and allied conditions, we should also see a marked improvement in the health and morals of the people in other directions.

But to return to the advantages of some system of modified notification, we gather from the last annual report of Dr. T. Orme Dudfield, the medical officer of health of the borough of Kensington, that he, too, would limit notification to those cases having expectoration, since he expresses his adherence with the view of Professor Koch that notification of consumption is necessary only where, owing to domestic conditions, the affected persons are sources of danger to people about them. This differentiation between "open" and "closed" tuberculosis has long been recognised in France, and the importance of insisting upon it in this country was recently remarked upon by Dr. C. Theodore Williams and Dr. H. T. Bulstrode in their joint report on the Paris Congress on Tuberculosis to the Lord President of the Council.[1] We see, too, by a circular recently issued to the profession in Kensington that Dr. Dudfield contemplates the consent of the patient to the notification, and in the event of the practitioner expressing a wish to that effect no visit will be paid to the house of the patient by a member of the sanitary staff. The circular in question adds that there will be no interference with the patient as the result of notification, either at his home or in connexion with his employment. In these circumstances the medical practitioners of the Royal borough will, we feel sure, heartily coöperate with the medical officer of health. We believe that the success which has attended voluntary notification in Liverpool for several years past is due to the fact that Dr. E. W. Hope, the medical officer of health, has adopted an attitude very much on the same lines as that indicated above. It must be remembered also that in whatever circumstances pulmonary tuberculosis is notified the difficulties of prolonged attention to cases will be great; as Dr. J. Niven of Manchester points out in his annual report for 1905, to sustain household visits month after month, perhaps for years, becomes very trying for all concerned, demanding great tact and management from the visitor as well as judgment on the part of the persons visited. But we

THE LANCET.

LONDON, SATURDAY, AUGUST 11, 1906.

The Neglect of Science.

IF the presidential address delivered before the British Association for the Advancement of Science at York last week did not contain any startling originalities or fresh facts, it was at least an acceptable synopsis of the present position of scientific work and a useful review of the labours of scientific men for the past quarter of a century. Professor E. RAY LANKESTER must have felt that the particular developments of scientific research which he chose to outline were probably well known to the majority of his hearers, so that it was at the risk of trying their patience that he traversed fields of discovery more or less remote from that with which his name is closely and honourably identified. In his sketch of the advances made in the various branches of science he devoted more attention to the wonderful and oft-told story of radium, of the acquisition of new elements, of their decay, of the discovery of helium, and so on, than to such subjects as the progress of our knowledge of cell substance, the discovery of new kinds of animals or plants, the recent developments in geological science, or the thesis that the phagocytes are our arms of defence against infective germs. Professor LANKESTER's point of view in science is, of course, that of the biologist and naturalist, and while he spoke lucidly on subjects with regard to which he repudiated any claim to authority, he referred to the workers in these fields in the spirit, as he said, "of a younger brother full of fraternal pride and sympathy in the glorious achievements of the great experimentalists and discoverers of our day." Professor LANKESTER asked the forbearance of his audience for choosing this course, a course which necessarily deprived his words of originality. It is not difficult to guess the considerations which prompted him to sum up not what has been going on merely in one workshop of science but in them all, yet we cannot but regret his action. That the history of science from beginning to end was, in spite of many difficulties, one clear record of advancement was the outcome of Professor LANKESTER's address; we would rather have received from a teacher of such force and humour a less obvious message.

He was, however, able to found a sound moral lesson upon the acknowledged progress made by science in all directions in recent years. "Where," he asked, "is the corresponding advancement of science in that signification of the word which implies the increase of the influence of science in the life of the community, the increase of the support given to it, and of the desire to aid in its progress, to discover, and then to encourage and reward, those who are specially fitted to increase scientific knowledge, and to bring it to bear so as to promote the welfare of the community?" It is the fact that science is not gaining advancement in regard to public and official consideration and support. It is only too obvious that the claims of science are being ignored by Ministers of State and by others in authority, while the public must be ignorant of the relations of science to the public weal, or popular representatives in Parliament and in office would not so often be wholly destitute of scientific knowledge. The failure of the public and of our leaders of industry to realise the immense practical importance of scientific research is a serious menace to the welfare and prosperity of the country. In many instances the people do not appear to understand the real nature and object of scientific inquiry; they regard it as a kind of hobby pursued by cranks for amusement, or by a glorified class of conjurers who intend to get rich upon patent rights; they divorce it altogether from serious purposes. When the fact is plainly brought home that people are dying by thousands from preventable disease it might be thought that generous support would be given to the organisation of research designed to alleviate the ill. The reverse prevails; neither the work nor the worker receives any large measure of public sympathy, and all endowment is left to a few public spirited individuals. The public never realises that the labourer in the field of science is worthy his hire. Honours, it is true, await the discoverer, but what a number of investigations there must be which are fruitless because of the lack of monetary support! Medical science has a stronger claim perhaps than any other province of research on the generosity of the public, and yet how niggardly is the response to all appeals for funds to carry out the work of combating disease by scientific methods.

Readers of THE LANCET will thoroughly endorse the view of Professor LANKESTER that if the people of this country wish to make an end of infective and other diseases they must take every possible means to discover capable investigators. They must discover them and employ them, and if good result is to be made at all certain it is probable that where a pound or so of public money is now spent it will be necessary to spend thousands We do not forget the munificent gifts to science which have been made on private initiative, and which have been productive of great benefits to humanity; but a less intermittent and a more princely supply of money is needed if the causes of preventive medicine and pathological research are to be organised on a fitting basis Nothing short of the annual allocation of a generous sum of money out of the public purse will serve the purpose, and the public should learn that it is a fundamental truth that on the successful prosecution of scientific research depend after all the health and welfare of the community.

The Notification of Pulmonary Tuberculosis.

THERE is now a very considerable number of towns in England in which pulmonary tuberculosis is notifiable in a voluntary sense, the notifier receiving the same fees as those paid under the Notification Act. In only one town, that of Sheffield, is such notification of pulmonary tuberculosis compulsory, and here the sting is withdrawn from the "compulsion" by the circumstance that the Act rendering the disease notifiable also provides that persons suffering from colleagues. The figures cited by the *Law Journal* and the general conduct of the force in relation to the injuries which so many of its members are called upon to sustain are alone sufficient to afford abundant reason for giving increased protection to the police, not only by an extended system of double patrolling in dangerous districts but also by a greatly increased severity of punishment for any ruffians by whom constables may be injured. The fact that plenty of men are willing to face the dangers of the service forms no reason for subjecting them to unnecessary exposure. It is true that the typical policeman is naturally fearless and that his confidence in his own prowess is enhanced not only by the consideration that the whole force of the law is at his back but also by the training which he has received in the arts of defending himself and of overcoming a criminal who resists him. Still, it is the business of his superiors to reduce the risks of his calling to a minimum. Our contemporary mentions as one of them, "the capture of mad dogs," which, although it was once real and serious enough, has now been happily obviated by the wisdom of the Minister who had sufficient courage and common sense to defy the clamour alike of politicians and of the more misanthropic of cynophilists and to apply medical science for the purpose of banishing rabies and hydrophobia from the kingdom.

Annotations.

"Ne quid nimis."

THE LATE SIR SYDNEY WATERLOW.

BY the death of Sir Sydney Hedley Waterlow, an ex-Lord Mayor of London, which took place at his residence, Trosley Towers, Wrotham, Kent, on August 3rd, at the ripe age of 84 years, the hospitals of London have lost a friend and the sick poor one who amidst all the turmoil of an exceptionally arduous business life found time to think of their needs As Vice-President of the Metropolitan Hospital Sunday Fund, and as chairman of the Distribution Committee of that Fund, he frequently presided over the meetings at the Mansion House when the Lord Mayor was unable to be present, and the manner in which he conducted the business of the meetings won the hearty approval of everyone, though of quite recent years it had become evident to his friends that the infirmities of age made the duties incidental to the post extremely arduous to him. Sir Sydney Waterlow was the founder of the famous firm of Messrs. Waterlow, Sons, and Co., Limited, stationers and printers, of Great Winchester-street, London, E.C., and for many years identified himself with the municipal life of the City of London. He was elected Lord Mayor in 1872, and was created a baronet in recognition of his services to the State by acting as the host of the then Shah of Persia, who visited England during his year of mayoralty. It is necessary to be middle-aged to remember the extraordinary enthusiasm that was aroused by the first visit to England of "The King of Kings," and the fact that it fell to Sir Sydney Waterlow's lot to welcome the gorgeous Oriental to the capital of our empire would have made his mayoralty memorable. By us, however, that same mayoralty will always be remembered for a totally different circumstance. In 1873 our repeated advocacy of the Hospital Sunday Fund movement, a good example of the possibilities of which existed in Birmingham, attracted the attention of the Lord Mayor, and as a result a consultation was held in the offices of THE LANCET between Sir Sydney Waterlow, Canon Miller, the head of the Birmingham movement, and the late Dr. James Wakley, then editor of THE LANCET, at which was discussed the establishment of a Hospital Sunday Fund for London on the lines of the similar fund in Birmingham. That meeting resulted in the foundation of the Metropolitan Hospital Sunday Fund—a fund with the work of which our readers are so familiar—and for the remainder of his long life Sir Sydney Waterlow never lost his keen interest in the magnificent project with the birth of which he had been so intimately associated. Indeed to his influence and efforts the Fund owes a great measure of its present successful position. Sir Sydney Waterlow was, however, a man of varied interests. On three occasions—viz., from 1868 to 1869, from 1874 to 1880, and from 1880 to 1885—he was a Member of Parliament, sitting first for Dumfries, then for Maidstone, and finally for Gravesend. He was a consistent Liberal throughout his Parliamentary career, and associated himself with many practical projects for the amelioration of the industrious poor. For example, he founded, and was chairman of, the Industrial Dwellings Company, and some years ago he presented Waterlow Park, Highgate, to the London County Council as a place of recreation for the people of London. In recognition of such public benefactions, and especially, perhaps, of his services as treasurer of St. Bartholomew's Hospital, he received from the King the decoration of K.C.V.O. in 1902. He was also a director of the Union Bank of London and of the London, Chatham, and Dover Railway Company, chairman of the governing body of the United Westminster Schools, and chairman of the Income-tax Commissioners of the City. This is a record of extraordinary activity and well-directed energy, and it is not surprising that Sir Sydney Waterlow's death has been felt by very many of all grades in life as a personal and real loss.

A YEAR'S WORK IN THE GYNÆCOLOGICAL DEPARTMENT OF THE KASR-EL-AINY HOSPITAL, CAIRO.

WHEN we take into account the fact that this hospital dates back to the year 1466, that it is of necessity lacking in many of the details of a modern hospital, and that the patients are drawn from the lowest ranks of native Egyptians, whose ideas on the subject of general and personal cleanliness are of the most primitive description, the disadvantages under which the staff have to carry on their work are obvious. For their nursing they are dependent on Egyptian girls trained in the nursing school attached to the hospital under the supervision of an English sister. In spite of these and other drawbacks incidental to the country the success which has been obtained reflects great credit on the surgical staff of the hospital. From a report drawn up by Mr. F. C. Madden, the senior surgeon, and Dr. N. E. Mahforz, assistant gynæcologist, we learn that during the year 1905 151 gynæcological operations were performed, including 55 abdominal sections with six deaths. These operations are performed with all aseptic precautions, silk or silkworm gut being the only ligature and suture materials employed. A considerable use is made of saline transfusion, and castor oil is found the safest and most effective post-operative aperient. Of 16 cases of dilatation for dysmenorrhœa and sterility no less than four of the patients subsequently became pregnant—an important point in a country in which sterility may be a reason for divorce. An interesting case of perforation of the uterus during the operation of dilatation of the cervix is recorded in which the uterus was removed by supravaginal hysterectomy, the patient making a good recovery. Bilharzial are not now writing upon the general utility of notification. Our object has been to accentuate the importance of a differentiation between "open" and "closed" tuberculosis, because if the distinction between the cases that will and the cases that will not (or probably will not) become sources of disease in their environment is properly regarded, the system of notification will be much more clearly understood by the public—which means that the work of both medical officer of health and of the general practitioner will be much simplified.

The Policeman's Risks.

IT has often been said of the profession of the law that it brings those who follow it into contact with some of the worst aspects of human nature and, as a natural consequence, leads them to think but badly of their fellow creatures. Our contemporary the *Law Journal* may perhaps be held to furnish an example of this kind when, in a sympathetic paragraph upon the risks incurred by policemen in the execution of their duties, it speaks of the force generally as being "unpopular." The paragraph further tells us that from 250 to 300 constables are so severely handled every year as to be kept upon the sick list for more than a week, that many of them receive injuries of a permanent character, and that the cases referred to are not a tithe of the whole, a statement which we can only interpret as meaning that injuries involving less than a week's sickness are received every year by some 3000 members of the force. If this be true, and with no official figures before us we can only hope that it is an exaggeration, the truth seems to indicate an almost criminal neglect on the part of the Home Office in not making better provision, by increased numbers or by different arrangements for the patrolling of dangerous districts, for the security of a conspicuously able and trustworthy body of public servants, long known to be weak in relation to the size of the district committed to its charge and to the enormous value of the property which it is called upon to protect. The combined metropolitan and city police districts cover an area of about 449,000 acres, or 700 square miles, and the rateable value of the metropolitan area, without the City, is £50,000,000 sterling, an amount which, of course, does not include the almost incalculable wealth contained in London and suburban dwelling-houses. The police-rate for this area is less than 3*d.* in the £. Alike for the protection of property and for the protection of the police themselves an increase of the force is urgently required. In many outlying portions of the district the number of men on duty is insufficient to afford protection from pilferers or burglars and in some of the centres of hooliganism or of crime the number is insufficient to secure the safety of the constables employed.

We cannot, however, agree with the *Law Journal* in regarding either the individual police constable, or the force to which he belongs, as "unpopular" in any proper or extended sense of the word. He is naturally unpopular with the thieves and the ruffians whose misconduct it is his duty to restrain; but by the enormous majority of the population he is regarded as a friend and protector. In the eyes of foreign visitors his ubiquity almost eclipses the traditional glories of the seldom seen "Lormaire" and eastern potentates are said to have described him as representing the ideal of beneficent despotism. He raises his hand and the whole traffic of Piccadilly is arrested for the safe passage of Betsy Jane and "his Majesty the baby." His uniform and unfailing civility, his kindliness to foreigners and provincials, his chivalrous care for the weak, the aged, and the infirm, are so much matters of course in London thoroughfares that those who constantly traverse them have ceased to wonder at conditions which are scarcely to be met with elsewhere, but which Londoners have come to accept as part of the ordinary amenities of life. Our contemporary contrasts the popular view of the policeman with the popular view of the soldier, whose march through the streets is escorted by crowds of admiring ragamuffins, and pronounces the policeman to be an object of "secret dislike." Even in the vilest neighbourhoods, when a policeman has been assailed by numbers, how often do we read that his whistle has been blown for him by some courageous girl or woman of the locality who has herself sometimes been made to suffer for her interference. We must admit that neither the individual policeman nor the procession emerging from the station on the way to duty is regarded as a street exhibition of enthralling attractiveness, but surely this depends chiefly or entirely upon the familiarity of the spectacle. The true relations between the force and the industrial classes of the metropolis can never be better seen than during the occasional progresses of "Sons of the Phœnix" and similar bodies when these are bent upon "demonstrating" against somebody or something in Hyde Park. The good-natured tolerance of the constables and the perfect readiness of the procession to obey orders and to submit to a control which will manifestly promote its arrival at its destination are generally evidences of perfect goodwill and appreciation on both sides, the constabulary respecting freedom and the processionists respecting legal and wisely exerted authority. We even doubt whether the lady "suffragettes," if that be the right name for them, would hesitate to admit in their cooler moments that the police in Cavendish-square had behaved with great forbearance under repeated provocation.

Thanks, in great measure, to the continuous endeavours of the St. John Ambulance Association, nearly the whole of the metropolitan police force has received instruction in rendering first aid to injured persons and has in this way acquired considerable practical knowledge of some aspects of the rudiments of surgery. Such knowledge might, it is evident, be in many circumstances misapplied for the benefit of those possessing it and would be invaluable to men who were disposed to exaggerate the severity of the injuries which they had received, or otherwise to practise any form of malingering. In the whole history of the force nothing is more creditable than the almost complete absence of any tendencies of this kind and the almost universal desire on the part of sick or injured policemen to return to duty at the earliest possible moment. In a body amounting, in all ranks, to about 18,000 men there must, of course, be occasional exceptions; but the general tone and tendencies of the force are absolutely hostile to them and the peccant individuals, as a rule, are too speedily eliminated to have any opportunity of doing mischief to their colleagues. The figures cited by the *Law Journal* and the general conduct of the force in relation to the injuries which so many of its members are called upon to sustain are alone sufficient to afford abundant reason for giving increased protection to the police, not only by an extended system of double patrolling in dangerous districts but also by a greatly increased severity of punishment for any ruffians by whom constables may be injured. The fact that plenty of men are willing to face the dangers of the service forms no reason for subjecting them to unnecessary exposure. It is true that the typical policeman is naturally fearless and that his confidence in his own prowess is enhanced not only by the consideration that the whole force of the law is at his back but also by the training which he has received in the arts of defending himself and of overcoming a criminal who resists him. Still, it is the business of his superiors to reduce the risks of his calling to a minimum. Our contemporary mentions as one of them, "the capture of mad dogs," which, although it was once real and serious enough, has now been happily obviated by the wisdom of the Minister who had sufficient courage and common sense to defy the clamour alike of politicians and of the more misanthropic of cynophilists and to apply medical science for the purpose of banishing rabies and hydrophobia from the kingdom.

Annotations.

"Ne quid nimis."

THE LATE SIR SYDNEY WATERLOW.

BY the death of Sir Sydney Hedley Waterlow, an ex-Lord Mayor of London, which took place at his residence, Trosley Towers, Wrotham, Kent, on August 3rd, at the ripe age of 84 years, the hospitals of London have lost a friend and the sick poor one who amidst all the turmoil of an exceptionally arduous business life found time to think of their needs As Vice-President of the Metropolitan Hospital Sunday Fund, and as chairman of the Distribution Committee of that Fund, he frequently presided over the meetings at the Mansion House when the Lord Mayor was unable to be present, and the manner in which he conducted the business of the meetings won the hearty approval of everyone, though of quite recent years it had become evident to his friends that the infirmities of age made the duties incidental to the post extremely arduous to him. Sir Sydney Waterlow was the founder of the famous firm of Messrs. Waterlow, Sons, and Co., Limited, stationers and printers, of Great Winchester-street, London, E.C., and for many years identified himself with the municipal life of the City of London. He was elected Lord Mayor in 1872, and was created a baronet in recognition of his services to the State by acting as the host of the then Shah of Persia, who visited England during his year of mayoralty. It is necessary to be middle-aged to remember the extraordinary enthusiasm that was aroused by the first visit to England of "*The* King of Kings," and the fact that it fell to Sir Sydney Waterlow's lot to welcome the gorgeous Oriental to the capital of our empire would have made his mayoralty memorable. By us, however, that same mayoralty will always be remembered for a totally different circumstance. In 1873 our repeated advocacy of the Hospital Sunday Fund movement, a good example of the possibilities of which existed in Birmingham, attracted the attention of the Lord Mayor, and as a result a consultation was held in the offices of THE LANCET between Sir Sydney Waterlow, Canon Miller, the head of the Birmingham movement, and the late Dr. James Wakley, then editor of THE LANCET, at which was discussed the establishment of a Hospital Sunday Fund for London on the lines of the similar fund in Birmingham. That meeting resulted in the foundation of the Metropolitan Hospital Sunday Fund—a fund with the work of which our readers are so familiar—and for the remainder of his long life Sir Sydney Waterlow never lost his keen interest in the magnificent project with the birth of which he had been so intimately associated. Indeed to his influence and efforts the Fund owes a great measure of its present successful position. Sir Sydney Waterlow was, however, a man of varied interests. On three occasions—viz., from 1868 to 1869, from 1874 to 1880, and from 1880 to 1885—he was a Member of Parliament, sitting first for Dumfries, then for Maidstone, and finally for Gravesend. He was a consistent Liberal throughout his Parliamentary career, and associated himself with many practical projects for the amelioration of the industrious poor. For example, he founded, and was chairman of, the Industrial Dwellings Company, and some years ago he presented Waterlow Park, Highgate, to the London County Council as a place of recreation for the people of London. In recognition of such public benefactions, and especially, perhaps, of his services as treasurer of St. Bartholomew's Hospital, he received from the King the decoration of K.C.V.O. in 1902. He was also a director of the Union Bank of London and of the London, Chatham, and Dover Railway Company, chairman of the governing body of the United Westminster Schools, and chairman of the Income-tax Commissioners of the City. This is a record of extraordinary activity and well-directed energy, and it is not surprising that Sir Sydney Waterlow's death has been felt by very many of all grades in life as a personal and real loss.

A YEAR'S WORK IN THE GYNÆCOLOGICAL DEPARTMENT OF THE KASR-EL-AINY HOSPITAL, CAIRO.

WHEN we take into account the fact that this hospital dates back to the year 1466, that it is of necessity lacking in many of the details of a modern hospital, and that the patients are drawn from the lowest ranks of native Egyptians, whose ideas on the subject of general and personal cleanliness are of the most primitive description, the disadvantages under which the staff have to carry on their work are obvious. For their nursing they are dependent on Egyptian girls trained in the nursing school attached to the hospital under the supervision of an English sister. In spite of these and other drawbacks incidental to the country the success which has been obtained reflects great credit on the surgical staff of the hospital. From a report drawn up by Mr. F. C. Madden, the senior surgeon, and Dr. N. E. Mahforz, assistant gynæcologist, we learn that during the year 1905 151 gynæcological operations were performed, including 55 abdominal sections with six deaths. These operations are performed with all aseptic precautions, silk or silkworm gut being the only ligature and suture materials employed. A considerable use is made of saline transfusion, and castor oil is found the safest and most effective post-operative aperient. Of 16 cases of dilatation for dysmenorrhœa and sterility no less than four of the patients subsequently became pregnant—an important point in a country in which sterility may be a reason for divorce. An interesting case of perforation of the uterus during the operation of dilatation of the cervix is recorded in which the uterus was removed by supravaginal hysterectomy, the patient making a good recovery. Bilharzial are not now writing upon the general utility of notification. Our object has been to accentuate the importance of a differentiation between "open" and "closed" tuberculosis, because if the distinction between the cases that will and the cases that will not (or probably will not) become sources of disease in their environment is properly regarded, the system of notification will be much more clearly understood by the public—which means that the work of both medical officer of health and of the general practitioner will be much simplified.

The Policeman's Risks.

It has often been said of the profession of the law that it brings those who follow it into contact with some of the worst aspects of human nature and, as a natural consequence, leads them to think but badly of their fellow creatures. Our contemporary the *Law Journal* may perhaps be held to furnish an example of this kind when, in a sympathetic paragraph upon the risks incurred by policemen in the execution of their duties, it speaks of the force generally as being "unpopular." The paragraph further tells us that from 250 to 300 constables are so severely handled every year as to be kept upon the sick list for more than a week, that many of them receive injuries of a permanent character, and that the cases referred to are not a tithe of the whole, a statement which we can only interpret as meaning that injuries involving less than a week's sickness are received every year by some 3000 members of the force. If this be true, and with no official figures before us we can only hope that it is an exaggeration, the truth seems to indicate an almost criminal neglect on the part of the Home Office in not making better provision, by increased numbers or by different arrangements for the patrolling of dangerous districts, for the security of a conspicuously able and trustworthy body of public servants, long known to be weak in relation to the size of the district committed to its charge and to the enormous value of the property which it is called upon to protect. The combined metropolitan and city police districts cover an area of about 449,000 acres, or 700 square miles, and the rateable value of the metropolitan area, without the City, is £50,000,000 sterling, an amount which, of course, does not include the almost incalculable wealth contained in London and suburban dwelling-houses. The police-rate for this area is less than 3*d.* in the £. Alike for the protection of property and for the protection of the police themselves an increase of the force is urgently required. In many outlying portions of the district the number of men on duty is insufficient to afford protection from pilferers or burglars and in some of the centres of hooliganism or of crime the number is insufficient to secure the safety of the constables employed.

We cannot, however, agree with the *Law Journal* in regarding either the individual police constable, or the force to which he belongs, as "unpopular" in any proper or extended sense of the word. He is naturally unpopular with the thieves and the ruffians whose misconduct it is his duty to restrain; but by the enormous majority of the population he is regarded as a friend and protector. In the eyes of foreign visitors his ubiquity almost eclipses the traditional glories of the seldom seen "Lormaire" and eastern potentates are said to have described him as representing the ideal of beneficent despotism. He raises his hand and the whole traffic of Piccadilly is arrested for the safe passage of Betsy Jane and "his Majesty the baby." His uniform and unfailing civility, his kindliness to foreigners and provincials, his chivalrous care for the weak, the aged, and the infirm, are so much matters of course in London thoroughfares that those who constantly traverse them have ceased to wonder at conditions which are scarcely to be met with elsewhere, but which Londoners have come to accept as part of the ordinary amenities of life. Our contemporary contrasts the popular view of the policeman with the popular view of the soldier, whose march through the streets is escorted by crowds of admiring ragamuffins, and pronounces the policeman to be an object of "secret dislike." Even in the vilest neighbourhoods, when a policeman has been assailed by numbers, how often do we read that his whistle has been blown for him by some courageous girl or woman of the locality who has herself sometimes been made to suffer for her interference. We must admit that neither the individual policeman nor the procession emerging from the station on the way to duty is regarded as a street exhibition of enthralling attractiveness, but surely this depends chiefly or entirely upon the familiarity of the spectacle. The true relations between the force and the industrial classes of the metropolis can never be better seen than during the occasional progresses of "Sons of the Phœnix" and similar bodies when these are bent upon "demonstrating" against somebody or something in Hyde Park. The good-natured tolerance of the constables and the perfect readiness of the procession to obey orders and to submit to a control which will manifestly promote its arrival at its destination are generally evidences of perfect goodwill and appreciation on both sides, the constabulary respecting freedom and the processionists respecting legal and wisely exerted authority. We even doubt whether the lady "suffragettes," if that be the right name for them, would hesitate to admit in their cooler moments that the police in Cavendish-square had behaved with great forbearance under repeated provocation.

Thanks, in great measure, to the continuous endeavours of the St. John Ambulance Association, nearly the whole of the metropolitan police force has received instruction in rendering first aid to injured persons and has in this way acquired considerable practical knowledge of some aspects of the rudiments of surgery. Such knowledge might, it is evident, be in many circumstances misapplied for the benefit of those possessing it and would be invaluable to men who were disposed to exaggerate the severity of the injuries which they had received, or otherwise to practise any form of malingering. In the whole history of the force nothing is more creditable than the almost complete absence of any tendencies of this kind and the almost universal desire on the part of sick or injured policemen to return to duty at the earliest possible moment. In a body amounting, in all ranks, to about 18,000 men there must, of course, be occasional exceptions; but the general tone and tendencies of the force are absolutely hostile to them and the peccant individuals, as a rule, are too speedily eliminated to have any opportunity of doing mischief to their organising committee are: (1) The Progress in Assistance for the Insane in Different Countries since 1902 to the Present Time; (2) the Organisation of Sections of Observation, Supervision, and Isolation in Asylums and Colonies and Methods which have given the Best Results; (3) Assistance for Convalescents; and (4) Assistance for the Feeble-minded, Alcoholics, Epileptics, and the Morally Insane. The subjects 1, 2, and 4 will be treated respectively by Dr. W. F. Menzies of Cheddleton Asylum, Dr. C. H. Bond of Ewell Colony for Epileptics, and Dr. W. W. Ireland, Dr. G. E Shuttleworth. and Dr. Fletcher Beach as representing this country. Other subjects for discussion will be: Out-patient Departments for the "Nervous" and Insane; Popular Sanatoria for the "Nervous"; Economic and Social Results of the Progress of Assistance for the Insane and especially Family Care; and the Function of the State in Assistance for the Insane. An exhibition of plans of asylums will be held; the London County Council will show plans of Long Grove Asylum prepared by its architect, Mr. G. T. Hine, who will also show plans of Kesteven and Hellingly Asylums, on the latter of which a paper will be communicated by Dr. H. F. Hayes Newington, alderman of the Sussex county council, and Dr. F. R. P. Taylor, the medical superintendent. The provincial administration of Milan will afford opportunities to the Congress to visit the asylum of Mombello and other institutions and a tour has been organised to the Italian lakes, with an opportunity to visit the asylum of Mendrisio, Switzerland. The Italian railways will make a reduction of 60 per cent. in the prices on their lines. Those who wish to join the Congress should at once inscribe their names by sending the subscription (20 francs) to the treasurer, Dr. Piero Gonzales, Via Leopardi 14, Milano.

SCHOOL CHILDREN AND HOME LIFE.

THERE is an admirable association in Manchester which provides health lectures for the people and a copy of one of these, delivered by Dr. R. T. Williamson, now lies before us.[1] The object of the lecture is, in Dr. Williamson's own words, "to draw attention to some of the ways in which the health of school children is impaired when school hours are over." The contentions are, of course, mainly written with a view to the requirements of day scholars but in many ways they also concern boarders Thus Dr. Williamson rightly lays stress upon the necessity for there being a sufficient interval allowed between the conclusion of dinner and the commencement of afternoon school. He points out how if this interval is not sufficiently long the scholars may suffer from indigestion, and are certainly sleepy and unable to fix their attention. This state of matters was common in nearly all schools 30 years ago, and to judge from the following amusing parody of a well-known stanza of Alcman is still in existence at Eton.

ALCMAN IN 2.45 SCHOOL.
εὕδουσι μὲν διδάσκαλοι,
χεὕδουσι μαθηταὶ
φιλ' ἀποδειπνίων·
εὕδω δὲ κἠγώ.[2]

Moreover, we have before us the time table of a very well-known and quite first-class school for girls, in which we note—

1.10 to 1.50, *or thereabouts*, dinner.
2.10 to 3.40, lessons.

We do not consider that 20 minutes is a long enough interval between dinner and lessons. Another point upon which Dr. Williamson insists is that there are too many home lessons, or what is the same thing too much work to be done out of school hours. On this matter we agree with him. Some amount of preparation out of schools-hours there must be, but in most elementary schools we believe that the time thus employed has been reduced to a minimum. At many more advanced schools, however, both day and public schools, the time given up to home lessons or preparation out of schools hours is far too long—that is, if it be added to the hours spent in school. Dr. Williamson's paper contains many other points which are most noteworthy by those who have the care of children. Among them he draws attention to the necessity for ventilation, especially of sleeping rooms. Sleeping with the open window is, of course, most desirable, but in many large towns, notably in London, it is difficult to carry out this procedure on account of the various noises, many of which are due to easily preventable causes.

THE CAUSE OF SUDDEN DEATH FOLLOWING THE INJECTION OF HORSE SERUM.

THOUGH the injection of the blood serum of the horse into man usually causes no serious inconvenience, yet in a certain proportion of cases it is followed by urticarial eruptions, pains in the joints, fever, swelling of the lymph nodes, œdema, and albuminuria. This reaction, which appears after an incubation period of from eight to 13 days, has been termed by Pirquet and Schick the "serum disease." In exceptional cases sudden death has occurred. In order to throw some light upon the cause of such accidents an important investigation of the subject has been made by Dr. Milton J. Rosenau and Dr. John F. Anderson in the Hygienic Laboratory of the United States Public Health and Marine-Hospital Service.[1] They have found that ordinarily horse-serum is a comparatively bland and harmless substance when injected into certain animals, but that it is possible to render them so susceptible that an injection of the serum may produce sudden death or severe symptoms. For example, a large quantity of horse serum may be injected subcutaneously or into the peritoneal cavity of a guinea-pig without causing the animal any apparent inconvenience. But if a guinea-pig is injected with a small quantity—e.g., $\frac{1}{250}$th cubic centimetre of the serum—and after the expiration of a certain interval of time is again injected the result will probably be fatal The first injection of horse serum appears to sensitise the animal in such a way as to render it very susceptible to a toxic principle in the serum. It is probable that on the first injection the proteid in the serum develops "antibodies" in the body of the animal and when these unite or react with the serum given at a second injection a toxic action is set up. It is noteworthy that an interval of from 10 to 12 days must elapse between the first and second injections, corresponding suggestively with the period of incubation of the serum disease noted by Pirquet and Schick, guinea-pigs remaining susceptible a very long time, at least 160 days. Guinea-pigs may be sensitised with very small quantities of horse serum; in most cases quantities varying from $\frac{1}{250}$th to $\frac{1}{1000}$th cubic centimetre were used and in one instance one-millionth of a cubic centimetre was sufficient to render a guinea-pig susceptible. It also requires very small quantities of horse serum when given in a second injection to produce poisonous symptoms. One-tenth of a cubic centimetre injected into the peritoneal cavity is sufficient to cause the death of a half-grown guinea-pig, while the same quantity injected subcutaneously is sufficient to produce serious symptoms. The symptoms produced by a second injection are respiratory embarrassment, paralysis, and convulsions, followed by death. They generally come on within ten minutes after the injection and when death results it usually occurs within an hour, frequently in infection of the genital organs is not an uncommon condition in Egypt, mainly, however, confined to the lowest class of women. Extensive vesico-vaginal and other fistulæ are frequent as the result of neglected labours. Ruptures of the perineum, on the other hand, are not common, for labours are often extremely easy, though on account of neglect in abnormal presentations or of contraction of the pelvis, the reverse may occur, in which cases very extensive injuries to the soft parts are met with. Ovarian cysts and fibroid tumours of the uterus usually attain a large size before coming under observation and the operations for their removal are correspondingly complicated and difficult. In the fatal case of ovariotomy there were masses of tubercle in the lungs and similar masses round the pancreas and liver. Of the two fatal cases of hysterectomy one died from a perforated duodenal ulcer, and in the other the bladder was accidentally injured during the operation, owing to the fact that it was much displaced by the tumour. The report indicates that good work is being done in this hospital and the staff are to be congratulated on their results.

MEDICAL MEN AND INDICTABLE OFFENCES.

THE Under Secretary of State for the Home Departmen has forwarded to us the following circular which has been addressed to all chief constables:—

> Whitehall, August 6th, 1906.
>
> SIR,—I am directed by the Secretary of State to inform you that the General Medical Council have asked to be furnished with notice of any medical or dental practitioner convicted of an indictable offence. This is done by the Prison Governors when the prisoner is committed to prison; in London, when he is fined, the Metropolitan police report the conviction, and the Secretary of State will be glad if you will give instructions that an intimation of any case coming to the knowledge of members of your force shall be sent to the General Registrar, 299, Oxford-street, London, whenever a fine is imposed on the defendant.
>
> I am, Sir, your obedient servant,
>
> The Chief Constables. M. D. CHALMERS

The keeping the roll of the medical profession free from undesirable characters is part of the duty of the General Medical Council, and it is necessary for that body to take active steps to obtain the necessary information. We do not imply that a conviction for every indictable offence renders a medical man unfit to pursue his profession, yet it is as well that such convictions should be registered by the General Medical Council.

THE HYPODERMIC INJECTION OF PREPARATIONS OF IRON.

IT is universally admitted that salts of iron, in virtue of their astringent and constipating properties, are sometimes badly borne by those persons for whom their use is most directly indicated. The large number of preparations of iron, both official and unofficial, organic and inorganic, in common use by various medical practitioners, and the diverse directions given by different authorities for the treatment of chlorosis and other forms of anæmia, afford an indication of the difficulties encountered. At one time it was recommended to prepare the patient suffering from anæmia and gastric disturbance, to whom iron was to be administered, by a preliminary course of purgatives and stomachics, but it is now more usual to start at once by giving preparations of iron. Later, much was hoped for from the introduction of organic iron compounds, and large numbers of such substances were extensively tried, but pharmacological experiments and clinical experience have agreed in demonstrating that there is little, if any, advantage in their use; indeed, Stockman regards inorganic iron compounds as more effective than organic in the treatment of anæmia, and not a few practitioners of great experience prefer the more astringent preparations to the milder and more bland. Now that the absorption of compounds of iron by the mucous membrane of the upper part of the small intestine has been definitely established and its excretion by the large intestine and the kidney has been traced, the view of Bunge as to the use of iron salts administered by the mouth in chlorosis—that they acted by sparing the hæmatogens or organic iron compounds of the food material from the action of the sulphuretted hydrogen in the bowel—must be regarded as controverted. In view, therefore, of the useful results which have been obtained by the hypodermic administration of other metals, such as mercury and arsenic, it becomes important to investigate whether iron may not with advantage be given by this means. It seems to have been employed in this manner by Rosenthal as long ago as 1872, and since that time various preparations of iron have been used hypodermically. The chief substances which have been employed for this purpose are dialysed iron, citrate of iron, citrate of iron and sodium, citrate of iron and ammonium, and various albuminates and peptonates, but most authorities regard the results obtained as hardly commensurate with the difficulties encountered. The injections are given into the thick tissues of the back and sometimes cause considerable pain unless the reaction is neutral. The solutions should always be freshly prepared and, of course, must be sterile. It should likewise be borne in mind that iron salts are toxic, and that smaller doses should be given hypodermically than by the mouth or rectum. In animals V. H. Mayers and F. Williams[1] observed vomiting, purging, a fall of blood pressure, coma, and death as a result of the action of toxic doses of iron and sodium tartrate, while Kobert and his pupils found that after injection of one milligramme of iron and sodium citrate per seven kilogrammes of weight in man 40 per cent. appeared unaltered in the urine. The possibility of renal irritation as a result of large doses must obviously be kept in mind. For purposes of injection, therefore, small doses only should be given, about 10 or 12 minims of a solution equivalent to from a quarter to half a grain of metallic iron. Da Costa found that a 20 per cent. solution of ferrous manganous citrate could be injected without pain and gave satisfactory results. He recommended 15 minims of the solution as a dose—that is, three grains of the salt. Other salts which have occasionally been tried are the lactate, salicylate, and cacodylate, but on the whole the results, as recorded, are disappointing of iron given by this means and a thoroughly satisfactory substance for injection has yet to be found. Chalboub gave the chloropeptonate of iron by the rectum, the solution being prepared by the addition of the perchloride of iron to peptone. On the whole, it seems that even with cases of irritability of the stomach the best results are obtained by the administration of preparations of iron by the mouth, and among the many substances at present in use, as a rule some one will be found to be effective. Professor T. Clifford Allbutt[2] states that he has found an old-fashioned French solution of malate of iron tolerated by patients "with queasy stomachs" when other ferruginous drugs are badly borne.

INTERNATIONAL CONGRESS FOR ASSISTANCE OF THE INSANE.

THIS Congress will be held at Milan from Sept. 26th to 30th. The meetings will be held in the Palais de l'Université Bocconi, Piazza del Statuto. In addition to the subjects for discussion proposed by the organising committee, of which Professor Tamburini of Reggio Emilia is president and Professor Ferrari of Bertalia, Bologna, is general secretary, the Congress will also discuss a proposition made by Dr. Frank of Zürich, the object of which is to found an international institute for the purpose of studying and combating the causes of mental diseases. The general subjects proposed for discussion by the were covered with tartar; the gums were red and swollen and there was a little pus in the pockets between the gums and the teeth. On the left pillar of the fauces was an ulcer with a greyish coating. On the internal surfaces of the cheeks at the level of the crowns of the teeth were two or three ulcers. There were no gastro-intestinal symptoms and no albuminuria. Mercurial stomatitis was suspected but the patient denied that she had taken mercury. Frequent cleansing of the mouth by the application of oxygenated water and the administration of potassium chlorate were ordered. The odour disappeared, the salivation almost ceased, and the ulcers began to heal. The patient left hospital on April 1st but returned on the 12th with another attack of stomatitis more intense than the previous one. She stated that she had not neglected to wash her mouth daily. The whole body was then minutely examined. In the subcutaneous fat of the right buttock a lump of the size of a hazel nut was discovered and in the left buttock a smaller one. The patient on being questioned stated that she had received an injection in the left buttock in March, 1905, and one in the right buttock in October. The urine was analysed and was found to contain a trace of mercury. The lump in the right buttock was excised and the stomatitis radidly improved. The lump was entirely subcutaneous and on section showed a greyish and yellowish surface hollowed out into little cavities. Microscopic examination showed that the lump was composed of fibrous tissue and that the cavities contained fat, crystals of calomel, and globules of metallic mercury. The delay in the appearance of the symptoms of mercurial poisoning is noteworthy.

[2] System of Medicine, vol v.

A TELEGRAM from the Governor of Hong-Kong, received at the Colonial Office on July 30th, states that for the week ending July 28th there were 5 cases of plague and 6 deaths from the disease. As regards the Mauritius a telegram from the Acting Governor received at the Colonial Office on July 31st states that for the week ending July 26th there was only 1 case of plague reported and that ended fatally.

THE Central Council of the British Medical Association has accepted the invitation of the Western branch to hold next year's annual meeting at Exeter and Dr. H. Davy has been nominated as president-elect. It is more than half a century since the British Medical Association visited Exeter.

AN Order of the Privy Council has been received by the Central Midwives Board continuing the present rules of the Board until Feb. 12th, 1907.

ABORTION FELONIOUSLY INDUCED BY DIACHYLON.

THE LANCET of July 28th, p. 248, contained a report of the trial at the recent assizes at Nottingham of a woman named Wardle charged with selling pills to pregnant women. Wardle was convicted and sentenced to 18 months' imprisonment with hard labour, the judge when passing sentence dwelling upon the serious nature of the offence, and pointing out to the prisoner that it was in his power to condemn her to penal servitude for life.

The case is of importance owing to the manner in which the prisoner's crimes were brought to the notice of the police authorities, and also on account of the nature of the drug used and of the manner in which it assisted in securing the conviction. Under the rules framed by the Central Midwives Board in accordance with the powers given to it by the Midwives Act, "In all cases of abortion a midwife must decline to attend alone and must advise that a registered medical practitioner be sent for," and whenever this is done it has to be noted in the midwife's record, a copy of which is to be forwarded to the local supervising authority (Rules 17 and 19). Further, "In all cases where a registered medical practitioner is not in attendance the midwife shall as soon as possible after the occurrence of a still-birth notify the same to the local supervising authority" (Rule 18). As certified midwives are liable to removal from the roll if they do not obey the rules cases of abortion and still-birth are likely to come under the observation of local authorities and if numerous should secure attention, as, in fact, happened at Nottingham. Uncertified midwives may still attend confinements for hire, so long as they do not hold themselves out to be certified, and they will be able to do so until April 1st, 1907, but after that date no doubt the notification referred to will constitute a more certain safeguard to the public than now. In the recent instance at Nottingham the pills used by the prisoner were roughly made up, varying from one and a half grains to five grains, and those analysed were found to be compounded of diachylon in proportions varying from 50 to 70 per cent., of aloes, and of a coating of boric acid. The women to whom they were supplied were told to take a dose of Epsom salts, fasting, in the morning, followed by four of the pills and by four pills again at night. In these circumstances it is not surprising that many of the women who had recourse to Mrs. Wardle in pregnancy, or supposed pregnancy, developed symptoms of lead poisoning and became very ill, while the frequent occurrence of lead poisoning, accompanied by abortion, attracted the notice of Dr. P. Boobbyer, the medical officer of health of Nottingham. These cases, moreover, were of noticeable frequency in Bulwell, an outlying district of the town, where it was found that a large trade was done in "Mrs. Seagrave's Pills," Seagrave being a trade alias of the prisoner Wardle. Not only were cases of lead poisoning among women of the child-bearing age occurring in extraordinary numbers, but no less than ten in which abortion had also taken place were cited to the local authority in order to prove to it the desirability of taking action.

When once it had been decided that the police should make inquiries the completion of the chain of evidence, by obtaining pills from the abortionist for analysis, by arresting her and seizing a large quantity of them at her house, and by obtaining the evidence of her victims, was not difficult; but the important feature of the case is the manner in which the medical officer of health was enabled to intervene in the interest of the public health confided to his care, owing to the statistics supplied to him under the Midwives Act. These statistics should draw attention to any systematic procuring of abortion taking place in other localities and the fact of lead having been used with such dangerous results at Nottingham may also afford an additional clue elsewhere. This use of the drug, however, either generally or in the form of diachylon, is not common if we may rely on our experience in the analysis of would-be abortifacients obtained in our investigation held in 1898.[1] We must not forget to call attention to the newspaper advertisements, less common now than formerly, but by no means stamped out, by which the quack establishes relations with his victims and which may also serve as a clue to those who seek to detect the criminal. The prosecution of a few newspapers on the ground of their complicity would do a great deal towards diminishing the revenues of the advertising abortionist, although it might not altogether do away with his trade.

One or two points raised in the defence of Wardle at Nottingham may be noted for the guidance of those who may have to meet similar suggestions upon other occasions. A number of witnesses, male and female, were called on her behalf, who swore that they had taken her pills with beneficial results for such ailments as "bad backs, internal pains, and anæmia." The general answer to evidence of this kind is, of course, that it in no way shows that the pills were not also sold with a view to procuring abortion, when they were asked for by pregnant women who desired them for that purpose. The evidence of the defendant herself upon this subject, who swore that she only sold them as "female pills" to be taken in cases of irregular or suppressed menstruation, was a matter for the jury to consider, and in this case it taxed their credulity too far.

---

[1] Quacks and Abortion, a series of articles on this subject commencing in THE LANCET of Dec. 10th, 1898, p. 1570.

ess than half an hour, and sometimes within a few minutes. The poisonous principle in horse serum appears to act upon the respiratory centres; the heart continues to beat long after respiration ceases. The toxic action bears no relation to diphtheria and the poison is not toxone. Though guinea-pigs cannot be rendered susceptible by previous injections with bacillus diphtheriæ, or by previous injections with diphtheria toxin, it appears that a mixture of diphtheria toxin and horse serum forms a more potent sensitising agent than horse serum alone. Dr. Rosenau and Dr. Anderson lay emphasis on the fact that diphtheria antitoxin is in itself harmless and plays no part in this poisonous action. The poisonous principle in horse serum is not affected by subjection to a temperature of 60° C. for six hours but it is destroyed at 100° C. in 15 minutes. It is filtrable through porcelain, is not injured by drying, and cannot be separated by precipitation with ammonium sulphate and subsequent dialysis. Serums eight years old are as toxic as those freshly prepared, and their poisonous action is not affected by exposure of the serum to x rays. It is probable that small quantities of horse serum are more powerful than large quantities in inducing susceptibility; in the latter case the guinea-pigs are probably partly immunised at the same time owing to slow absorption of the serum. An active immunity against the toxic principle may readily be established by repeated injections of horse serum at short intervals but up to the present it has not been found possible to transfer this immunity in the blood serum or body juices to another guinea-pig. This investigation has also revealed the remarkable fact that guinea-pigs may be rendered susceptible to the toxic action of horse serum by feeding them with horse serum or horse meat. This opens up an interesting question as to whether sensitive guinea-pigs may also be poisoned by feeding them with the same serum after a proper interval of time. It is suggested that if man can be sensitised in a similar way by eating certain proteid substances some light may be thrown upon those interesting and obscure cases in which the eating of fish and other articles of diet habitually causes sudden, and sometimes serious, symptoms. It is interesting also to note that the susceptibility to the toxic action of horse serum is transmitted by heredity from a mother guinea-pig to its young, a fact which may throw some light upon the well-known hereditary tendency to tuberculosis in children born of a tuberculous parent. Dr. Rosenau and Dr. Anderson allow the possibility that man may not be sensitised in the same way as guinea-pigs. Man reacts to the first injection of horse serum after from eight to 13 days. Guinea-pigs show no reaction as a result of a first injection; both man and guinea-pigs react to a second injection. But the reactions in man and in guinea-pigs differ both in severity and in kind, so that the relation of the foregoing observations upon the guinea-pig to man must await further investigation.[1]

MATERNAL IGNORANCE IN THE MANUFACTURING DISTRICTS.

THE ignorance of the working-class women of the manufacturing districts as to the feeding and care of their infants is almost incredible and is a lasting disgrace to those who have had the planning of their education. Teachers, knowing none too much of such matters themselves, have had to steer by "the Code," even if they wished to impart some useful knowledge, and one of the chief causes of the murderous infantile death rate has thus been perpetuated. "The other week it came out at an inquest at Gorton," writes a local and valued correspondent, "that the mother had fed her 14 months old child only three times a day, and not at all in the night, with a few tablespoonfuls of milk and barley water. Dr. J. J. O'Shea said that the cause of death was exhaustion due to insufficient feeding, which in other words means death from starvation. The jury thought the parents should be censured and the coroner accordingly administered a mild reproof." The parents in these cases should be made to feel their responsibility in some effectual way. Many of them might do better if they would and they should be taught that neglect and even ignorance of their duty are not only wrong but punishable. Our correspondent shows that infant life is held cheaply in Manchester and its neighbourhood, and no doubt familiarity with a high infantile mortality tends to blunt the feelings. It is cheering, however, to note that more attention is being paid to this subject. The Mayor of Colne has just set an example that many other places and municipal authorities would do well to follow. He will defray the entire expense of a trained nurse, as to salary, uniform, and board, for the term of five years, the duty of the nurse being primarily attention to infants. More common sense in education and a higher moral tone among the mothers would soon reduce the death-rate.

THE MEDICO-LEGAL SOCIETY AND DEATH CERTIFICATION.

AT a recent extraordinary meeting of the Medico-Legal Society, Mr. Troutbeck, the treasurer, being in the chair, the following resolutions were passed unanimously on the motion of Sir William J. Collins, M.P., seconded by Mr. R. Henslowe Wellington:—

1. That the present methods (under Coroners and Deaths' Registration Acts) of ascertaining the fact and cause of death are imperfect, constitute grave public dangers, and call for early legislation, with a view to the amelioration of the law.

2 That a deputation from the Medico-Legal Society wait upon the Lord Chancellor in order to represent to him this view of the society, the deputation to consist of the officers, the ex-president, and the Council. That the learned President (Mr. Justice Walton) be requested to approach the Lord Chancellor as to the reception of the deputation.

3 That a copy of these resolutions be transmitted to the public control committee of the London County Council.

These resolutions were the outcome of opinions expressed at a previous meeting of the society, when there was a discussion on the Methods of Ascertaining the Fact and Cause of Death. A committee was appointed for the purpose of considering certain of the proposals which had been made during the discussion and upon the report of this committee the above resolutions were passed.

STOMATITIS DUE TO A MERCURIAL INJECTION GIVEN FIVE MONTHS PREVIOUSLY.

THE dangers of mercurial injections do not seem to be appreciated sufficiently. When an insoluble preparation is used a toxic quantity of mercury is deposited in the body which usually is slowly absorbed, producing only therapeutic results; but sometimes rapid absorption takes place and serious and even fatal results are the consequence. Of the cause of this rapid absorption little is known and untoward consequences are therefore impossible to foretell. We have recently referred to a fatal case of injection of "grey oil," and also to one in which serious symptoms were checked in the only possible way, by excision of the mercurial deposit.[1] At a meeting of the Société Médicale des Hôpitaux of Paris on June 22nd M. P. Menetrier and M. Bouchard reported a case in which this operation was necessary in a case of stomatitis due to a mercurial injection given five months previously. A woman, aged 38 years, was admitted into hospital on March 22nd, 1906. On admission the breath was fœtid and there was abundant salivation, and mastication was painful. The tongue was furred and swollen; the teeth

---

[1] The authors state in a *postscript* that a paper by R. Otto, entitled "Das Theobald Smithsche Phänomen der Serum-Ueberempfindlichkeit," reprinted from Leuthold-Gedenkschrift, Band i., which came to their notice after the galley proof of their paper had left their hands, deals with some of the same problems and contains many results in harmony with their own.

With regard to the use of lead, however, the prosecution, with the judge's approval, exercised their right to call rebutting evidence, and Dr. Boobbyer went into the witness-box to point out that as anæmia was one of the earliest and most constant symptoms of lead poisoning it was inconceivable that lead administered to an already anæmic patient should fail to make him or her worse instead of better, while absence of menstruation is due practically either to pregnancy or anæmia.

Upon other points also arising out of the use of diachylon it was possible to supply answers to the defence. In her evidence Wardle declared that she only employed it in order to make her pills hold together, and that she knew nothing of its specific action or that it contained poison. The reply to this, upon which we note the judge laid considerable stress in his summing up, was that as Epsom salts are an acknowledged eliminative of lead, it was strange that the prisoner should have recommended them if she were in complete ignorance that diachylon contained lead.

The only other point to which we need call attention is to the fact that the jury in finding the prisoner guilty recommended her to mercy. The ground upon which they did this is not stated in the report before us, but it will seem to many to be indicative of a semi sympathetic attitude towards this class of crime which is undoubtedly to be found in many districts. This attitude, of which those practising at the bar in criminal courts are well aware, often renders convictions difficult to obtain, and makes it desirable that the evidence brought forward should be as irresistibly conclusive as possible. It accounts to some extent for the supineness of local and other authorities who allow a noxious and criminal trade to be carried on so openly that it can be advertised in the public press with impunity.

We have referred above to the part played in the recent prosecution by the medical officer of health, and by the reports furnished under the Midwives Act. To this we would add that although we have no desire to see medical practitioners playing the part of detectives, we see no reason why their cordial coöperation should be withheld where the detection and prevention of the crime of abortion are concerned. All practitioners are as deeply concerned in the protection of the public unofficially as is the medical officer of health by virtue of his position, and the felony in question is one the commission of which by others lays them open to peculiar danger. The position of the medical practitioner who is called in to attend a case in which he suspects its commission is an anxious one. He must respect absolutely the confidences of his patient, yet he knows that, if his suspicions are well grounded, the preservation of silence may at any time lay him open to the charge of being himself the felon or, at any rate, of complicity should the matter come to light. The guilty ones will only be too glad to see him accused or to set the accusation on foot if thereby they can save their own skins. He must be guided as to the course he may take by the exercise of all discretion and by the circumstances of the particular case which concerns him; but we cannot readily assent to the suggestion that a medical man's professional obligations may involve his shielding, at the risk of his own liberty or of his honourable reputation, a criminal who is dangerous to the public. But to separate the criminality of the abortionist from that of the willing subject must be very difficult, while the subject will stand in the sacred relation of patient towards the medical man.

METROPOLITAN HOSPITAL SUNDAY FUND.

A MEETING of this Fund was held on August 2nd at the Mansion House, Sir HORATIO DAVIES, in the absence of the Lord Mayor, presiding. Among those present were Sir Stephen Mackenzie, Sir E Durning Lawrence, Sir William S. Church, Bart., Sir John C. Bell, Sir Savile Crossley, Bart., the Hon. Sydney Holland, Dr. J. G. Glover, and Mr. A. Willett. Letters of regret were read from Archdeacon Sinclair, the Chief Rabbi, the Rev. C. H. Grundy, Mr. T. Wakley, senr., and others.

The chief business of the meeting was to approve of the report of the distribution committee and to recommend that the awards should be paid as soon as possible

Sir DURNING LAWRENCE, chairman of the Royal Waterloo Hospital for Children, called attention to the small sum awarded to his hospital and hoped that the committee would see its way to enlarge the grant.

Sir WILLIAM CHURCH pointed out that the hospital authorities had held a bazaar in aid of the hospital just before Hospital Sunday which realised £8000. This contravened a rule of the constitution of the Hospital Sunday Fund.

Sir DURNING LAWRENCE denied that the date of the bazaar had been fixed by the hospital. The bazaar had been opened by Royalty and the hospital authorities had no control over the date.

Dr. GLOVER called attention to the large number of out-patients treated at the London Hospital. Many of these, he felt sure, must be able to provide medical attendance for themselves. He also referred to the withholding of the grant to Charing Cross Hospital. It was a very serious matter for the London poor.

Mr. HOLLAND denied that there was any abuse of the out-patient department at the London Hospital and pointed out that there was only one other hospital for adults in the East of London. The only way to reduce the number of out-patients at the London Hospital would be to build more hospitals.

Eventually the report was adopted.

The annual report of the committee of distribution to the council of the Metropolitan Hospital Sunday Fund, 1906, stated that the committee of distribution desired to record with regret the resignation of Sir Felix Schuster, Bart., who is now unable to give the necessary time to the work of the Fund. Mr. George Herring had again most liberally offered to add one-fourth to the amount collected in places of worship, as well as to the City collection. The amount of the Fund to the present time was £56,303, to which had to be added the sum of £3000, a portion of the legacy of £10,000 left to the Fund by the late Mr. Herbert Lloyd, making a total of £59,303. This year 250 institutions had made applications for grants from the Fund, being two more than in 1905, in addition to the nursing associations. Two hospitals which applied for grants were considered ineligible. The committee, though fully realising the excellent work carried on by the Cancer Hospital, had not made an award this year, the hospital not being in want of funds at the present time. The committee recommended the distribution of £57,510 to 161 hospitals and institutions, 60 dispensaries, and 26 nursing associations. The committee recommended that the award to *Charing Cross Hospital* should be paid when it was proved to its satisfaction that the result of the special appeal to be made next autumn would enable the committee to carry on the work of the hospital. The committee recommended that the grant made last year should be paid to the City Orthopædic Hospital without waiting for the amalgamation to be carried through. 5 per cent. of the total sum collected was set apart to purchase surgical appliances.

The following are the particulars of the awards recommended by the committee of distribution :—

GENERAL HOSPITALS.

	£	s.	d.
Charing Cross Hospital	1204	13	9
French Hospital	356	5	0
German Hospital	690	12	6

the law" as every man by law is assumed to be, we may int out that the liability of the medical man towards patient, upon which actions are brought such as that Crier v. Hope and Currie, commented upon in THE LANCET July 28th, is based upon allegations of "negligence." In her words, it is as necessary that negligence should be oved to the satisfaction of a jury in an action of this nd against a medical man in order to constitute a "cause action" as it is when one man sues another for running er him in the street. If the running over is a pure acci-nt—due, for example, to a horse bolting through being ightened by lightning—there is no liability, and justly so. he Employers' Liability Act is referred to in the passage oted, so we may add that the Employers' Liability Act d the Workmen's Compensation Acts provide in certain asses of employment and in certain defined circum-ances that an employer shall be liable for injuries sus-ined by his servant in the course of his employment, hen under the common law no such liability would exist. or example, these Acts, where they apply, may enable a ervant to sue his employer on account of injuries caused by he negligence of a fellow servant. An employer is liable to trangers at common law for injuries caused to them by his ervant's negligence in the course of his employment, as verybody knows, or should know, but not when one ervant injures another in the same employment. We eed hardly point out that the relations of a patient o his medical man are not those of master and servant. njury arising to a medical man from attending upon patient can rarely arise through negligence on the art of the latter only, without any intention of running risk on the part of the former, and there would e plenty of occasion at the trial of such an action or the airing of the well-worn legal saying, "Volenti on fit injuria," which might be applied generally by saying hat those who enter of their free will into a dangerous pro-ession must accept the perils which arise out of it. They ust endure without complaining such personal suffering as may be the natural result of what they have undertaken to do.

BRITISH MEDICAL BENEVOLENT FUND.

AT the July meeting of the committee 22 applications were considered and grants amounting to £161 were voted in relief, one case being postponed for further inquiries. Appended is a short abstract of the cases assisted :—

Daughter, aged 54 years, of late M.R.C.S. Eng., L.S.A., who practised in Bucks. Used to be a governess but is now unable to teach on account of deafness and can only earn a few shillings a week by needlework. Relieved five times, £56. Recommended by Lady Milbank. Voted £10 in ten instalments.

Widow, aged 50 years, of M.R.C.S. Eng., L.S.A., who practised in London. No income; indifferent health; no children. Quite unprovided for at husband's death a few years ago. Relieved twice, £24. Recommended by his Grace the Archbishop of York. Voted £12 in 12 instalments.

Widow, aged 62 years, of L.R.C.P. Lond., L.R.C.S. Edin., who practised in London. No income; only son, aged 42 years, is barely able to support himself on account of mental weakness. Earns a few shillings a week by needlework. Husband's means exhausted by six years' illness before death. Recommended by Mr. Percy Warner. Voted £10 in ten instalments.

Daughters, aged 63 and 65 years respectively, of late L.R.C.P., L.R.C.S. Edin., who practised in Scotland. At father's death, 22 years ago, the younger sister obtained a certificate for teaching and for 22 years has been head mistress in a State aided episcopal school but is now obliged to retire (on account of age) with a pension of £20 per annum. The elder sister is living with her, attending to the household duties, and has assisted for many years in the charge of a resident patient. Recommended by Sir Hector Cameron. Voted £18 in 12 instalments.

Daughter, aged 45 years, of late M.R.C.S. Eng., who practised in Oxfordshire. Income less than £3 a year and since her father's death some years ago has supported herself by taking situations as servant, &c., but has now had an accident by which she is temporarily incapacitated. Recommended by Miss Kinglake. Voted £5.

Widow, aged 54 years, of L.K.Q.C.P. Irel., who practised in Bucks. Practically unprovided for at husband's death. Has endeavoured to establish a nursing home and is now trying to obtain situation as a companion. Recommended by Dr. William Travers. Voted £5.

Daughter, aged 21 years, of late L.R.C.P., L.R.C.S. Edin., who practised in Jamaica. Has been obliged to give up a situation as draper's assistant on account of severe dyspepsia and nervous exhaustion from carious teeth. Is advised to have 23 teeth extracted and replaced by artificial ones and asks for help to get this done. Recommended by Mr. Edward East and Mrs. Evelyn Martin. Voted £5.

Widow, aged 45 years, of L.S.A., who practised in London. Quite unprovided for at husband's death two years ago. Small earnings from needlework; ill health and bad sight. Two sons, aged 19 and 14 years respectively, barely self-supporting. Relieved once, £12. Recommended by Dr. J. A. Ormerod. Voted £14 in 13 instalments, £2 being an emergency grant.

Widow, aged 52 years, of M.B. Cantab., who practised in London. No provision at husband's death five years ago and has supported herself with a little help from this Fund and from friends and by washing and other work. Five children, of whom three are in domestic service, one a boy, earning 6s. a week is an apprentice, and the fifth, a daughter, aged five years. Relieved three times, £41. Recommended by Mr. J. Roche Lynch. Voted £12 in two instalments.

Widow, aged 55 years, of L.R.C.P. Lond., L.R.C.S. Irel., who practised in South Wales. At husband's death a few years ago had £300 insurance money but has spent a considerable portion of this to maintain and educate a daughter, who is studying cookery and laundry work, with a view to teaching these subjects under a county council. Ekes out small income from the remainder of her capital by letting lodgings and the help received from a Masonic fund. Relieved once £5. Recommended by Dr. A. Sheen, vice-president. Voted £5.

Daughter, aged 57 years, of late M.R.C.S. Eng., L.S.A., who practised in Staffordshire. Endeavours to support herself by literary work. Indifferent health. Relieved once, £12. Recommended by Dr. J. Pickett. Voted £5.

Daughter, aged 58 years, of late M.R.C.S. Eng., L.S.A., who practised in Warwickshire. Supported herself for many years as a dispenser but now finds it impossible to get work on account of her age. Only income about £15 a year, being the interest on savings. Relieved once, £10. Recommended by Dr. H. F. Haynes. Voted £10 in ten instalments.

Widow, aged 35 years, of M.R.C.S. Eng., L.R.C.P., who practised in London but was incapacitated for some years before death. Applicant maintains herself as a working housekeeper but has been recommended to have a short rest. Two children, aged 15 and 11 years respectively. Relieved twice, £23. Recommended by Mr. S. H. Bram. Voted £5.

Daughter, aged 56 years, of late M.R.C.S. Eng., L.S.A., who practised in Hants. Income £15 a year and receives a little help from brothers. Endeavours to earn a few shillings a week by needlework but finds her eyesight is failing. Relieved once, £6. Recommended by Dr. W. R. Grove. Voted £5 in two instalments.

Daughter, aged 25 years, of late M.D., who practised in Middlesex. Unable to earn her living on account of ill-health and dependent on a mother with a very small income. Relieved once, £10. Recommended by Dr. H. A. Sansom. Voted £5.

Daughter, aged 59 years, of late M.R.C.S. Eng., L.S.A., who practised in Hampshire. Used to be a governess but unable to obtain pupils any longer. Tries to supplement a pension of £20 per annum from a charity by letting rooms. Relieved nine times, £76. Recommended by Sir Constantine Holman, vice-president. Voted £3.

Widow, aged 50 years, of L.S.A., who practised in Notts. At husband's death, nearly 20 years ago applicant trained as a maternity nurse with the aid of a grant given by this fund and has supported herself ever since, but two years ago invested her savings in a registry office, which has not been a success. Two daughters, aged 21 and 17 years respectively, barely self-supporting. Relieved once, £12. Recommended by Mr. Edmund Owen, vice-president. Voted £6.

Widow, aged 65 years, of M.D. St. And., M.R.C.S. Eng., who practised in London. No income and dependent on children. Relieved five times, £86. Recommended by Mr. E. Parker Young and by Mr. H. W. Kiallmark. Voted £12 in 12 instalments.

Widow, aged 60 years, of L.R.C.P. Edin., L.F.P.S. Glasg. Dependent on a pension of £20 a year from a charity and occasional help from a son earning a small weekly wage. Relieved nine times, £95. Recommended by Dr. F. W. Tatham. Voted £10 in ten instalments.

Daughter, aged 50 years, of late M.R.C.S. Eng., L.S.A., who practised in London. Has supported herself for 30 years by nursing but is now incapacitated by ill-health and dependent on a niece who lets lodgings to maintain herself and a consumptive brother. Relieved twice, £15. Voted £2 as an emergency grant, the case to be considered again at the next meeting.

ASYLUM REPORTS.

Asylum for the Counties of Salop and Montgomery and for the Borough of Wenlock (Sixty-first Annual Report for the Year 1905).—The reports of the visiting committee of this asylum deal largely with the question of providing increased accommodation. At the close of 1905 the asylum contained 801 patients, or 50 more than the numbers provided for; at the same date 65 patients were boarded out elsewhere. The committee is of opinion that it is advisable to enlarge the present institution to accommodate 200 more patients and has notified the county councils to this effect. It likewise recommends the latter to unite with several other local authorities in adapting a residence in the neighbourhood of Birmingham for the purpose of an asylum for idiot and imbecile children—a very wise proposal. The report of the medical superintendent, Dr. Daniel F. Rambaut, states that the admissions numbered 230, the largest annual admission-rate in the history of this asylum. The recoveries were in the proportion of 33·91 per cent. (males) and 36·46 per cent. (females) of the admissions. 86 per cent. of those discharged recovered had been resident less than 12 months. The average daily number resident was 785. The causation of insanity in, and the character of, the admissions are not referred to in the report, but from the statistical tables it appears that only 29 of the total admissions had the "insane

MEDICINE AND THE LAW.

Infection from Milk.

DURING recent years several outbreaks of infectious disease have been traced to milk which has been shown to be the means of spreading such diseases among the persons who consume it. Scarlet fever is one of the diseases most commonly spread in this way. It is clear that the germs of that disease occasionally find their way into milk and they seem to thrive in it. These germs may get in either because some person suffering from scarlet fever has been milking the cows or has otherwise been brought into contact with the milk, and it has also been thought that the disease may be caused by the animal being itself the source of infection. In the case of a recent outbreak the source was traced to the farm from which the milk came, when it was found that one of the household was suffering from scarlet fever, and the farmer was unaware of the fact until the medical officer of health arrived on the scene from the district in which the infection had been spread. Besides scarlet fever there are other diseases, the germs of which grow and are conveyed in milk. Of these, typhoid fever, tuberculosis, and diphtheria appear to be the chief. The germs of typhoid fever usually find their way into milk from the water which is either used to wash the vessels into which the milk is put, or is added for the purpose of dilution. Much, of course, can be done to prevent the spread of infectious disease from milk by having the dairies and cowsheds kept thoroughly clean and well ventilated, and this can be effected by the sanitary authorities acting under the orders made pursuant to the Contagious Diseases (Animals) Act, 1886, Section 9 which was not repealed by the consolidating Act of 1894. Experience, however, has shown that even these powers are not sufficient to check the spread of infection, and there are additional powers in Section 4 of the Infectious Disease (Prevention) Act, 1890, and also as regards London in Section 71 of the Public Health (London) Act, 1891. It is questionable, however, whether these powers are sufficient Statutes can afford assistance in two ways. They can confer on the medical officers of health powers of inspection and of obtaining information, and they can also enable them to stop the supply coming from an infected dairy until the cause of infection has been removed. Section 4 of the *Infectious Disease* (Prevention) Act, 1890, enacts that in case the medical officer of health is in possession of evidence that any person in the district is suffering from infectious disease attributable to milk supplied within the district or from any dairy situate within or without the district, or that the consumption of milk from such dairy is likely to cause infectious disease to any person residing in the district such medical officer shall, if authorised in that behalf by an order of a justice having jurisdiction in the place where such dairy is situate, have power to inspect such dairy, and if accompanied by a veterinary inspector or some other properly qualified veterinary surgeon to inspect the animals therein. If on such inspection the medical officer of health shall be of opinion that infectious disease is caused from consumption of the milk supplied therefrom, he shall report thereon to the local authority and his report shall be accompanied by any report furnished to him by the said veterinary inspector or veterinary surgeon, and the local authority may thereupon give notice to the dairyman to appear before it within such times not less than 24 hours as may be specified in the notice to show cause why an order should not be made requiring him not to supply any milk therefrom within the district until such order has been withdrawn by the local authority. If in the opinion of the local authority he fails to show such cause then the local authority may make such order as aforesaid; and the local authority shall forthwith give notice of the facts to the sanitary authority and county council (if any) of the district or county in which such dairy is situate and also to the Local Government Board. Any person refusing to permit the medical officer of health on his production of such order to inspect any dairy, or if so accompanied to inspect the animals kept there, or if after any such order not to supply milk has been given supplying any milk within the district in contravention of such order, shall be deemed guilty of an offence against this Act. The order is to be withdrawn immediately the cause of infection is removed. The word "dairy" includes any farm, farmhouse, cowshed, milkstore, milkshop, or other places from which milk is supplied or in which milk is kept for purposes of sale, and "dairyman" includes any cowkeeper, purveyor of milk, or occupier of a dairy. A medical officer of health, if he suspects that milk is the cause of the disease, will act on his own initiative without waiting for a justice's order. It would be an advantage if local authorities had the power to obtain a list of customers from a dairyman whose milk is suspected; they would then be able more easily to tell whether or not the milk was the actual cause of the disease. It will be noticed that in the section above quoted the local authority can only stop the dairyman from sending milk into its own district. There is nothing whatever to prevent him from sending it into any other urban or rural district in the country. No doubt the proper remedy is to stop the sale of the infected milk entirely. This might be done either by the sanitary authority of the district or by the Local Government Board. It would seem, therefore, that if any amendment of the law is required it should be in the direction of giving the medical officers of health greater powers to discover the source of infection, so that if it is due to milk they should learn the fact at once and immediately inform the purveyor. Urban and rural district councils are the local authorities charged with carrying out and enforcing the Dairies, Cowsheds, and Milkshops Order of 1888 made by the Privy Council, the powers of which in this respect have since been transferred to the Local Government Board. Under these orders the council is required to keep a register of persons carrying on the trade of cowkeepers, dairymen, or purveyors of milk, and persons carrying on those trades without being registered are liable to penalties. A person, however, who only keeps cows or a dairy for the purpose of making and selling butter or cheese and not for selling milk is not treated as a cowkeeper or dairyman for this purpose. If disease exists among the cattle in a dairy or cowshed or other place the milk of a diseased cow is not to be mixed with other milk, or sold or used for human food or (unless it has been boiled) sold or used for the food of swine.

Actions against Medical Men by their Patients and Vice Versâ.

From time to time medical men struck by the obvious hardship of an action brought against a member of their profession by a former patient suggest in the public press that the case should sometimes be reversed and that an action should be brought by a medical man on account of suffering resulting to him in the pursuit of his practice. We have ourselves received letters to this effect and one recently appeared in the *Pall Mall Gazette*, signed "M.D.," which contained the following passage: "In a case in which a medical man has undoubtedly caught, say, scarlet fever, from a patient, could that patient be sued for damages by the medical attendant under the Employers' Liability Act? It seems to me—not being versed in the law—that this suing game can be played by both sides, doctor and patient." To many the answer will be obvious, but to others who like "M.D." are not as "versed

Looking Back.

FROM

THE LANCET, *SATURDAY*, August 9th, 1828.

THE FIRE PROOF MAN.

THE French Medical Journal, *La Clinique*, gives an account of the experiments of M. Martinez, the fire-proof man, as he is called, who is now one of the principal objects of attraction at Paris. M. Martinez is not, like the celebrated Russian salamander, Chamouni, insensible, for a given period, to the effects of heat; on the contrary, he suffers so much exhaustion from his experiments, that he is only able to repeat them once a week. He assumes the title of "Incombustible"; but after the fate of Chamouni, it may reasonably be doubted whether any man can fairly lay claim to the privilege of being fire-proof. The Russian salamander was remarkable for the simplicity and singleness of his character, as well as for that idiosyncrasy in his constitution, which enabled him, for so many years, not merely to brave the effects of fire, but to take delight in an element where other men find destruction. He was above all artifice, and would often entreat his visitors to melt their own lead, or boil their own mercury, that they might be perfectly satisfied of the gratification he derived from drinking those preparations. He would also present his tongue, in the most obliging manner, to all who wished to pour melted lead upon it, and stamp an impression of their seals. His merit, however, was never sufficiently acknowledged, till he was found dead in the oven which he so often entered to amuse his visitors, by what he called his grand experiment,

> "Urit enim fulgore suo qui prægravat artes
> Infra se positas, extinctus amabitur idem."

This grand experiment was to enter an oven with a raw leg of mutton, and not to retire from it till the joint was thoroughly baked. Chamouni entered the oven once too often; his ashes were collected, and conveyed to Mojaisk, his native town, where a neat monument has been erected to his memory, and a well-written Latin inscription commemorates his fate.

M. Martinez, the French salamander, says *La Clinique*, was born at the Havannah; he is 43 years of age, about five feet high, and appears to be of a robust constitution. He has the complexion and features of a Creole; his nose is flat, and, at present, somewhat disfigured by sores produced by the bursting of a thermometer, which was imprudently carried too near his person, at a late experiment, in order to ascertain the temperature of his body. M. Martinez, in his youth, followed the trade of a baker, and from the age of nine to twelve years, was constantly in the habit of exposing himself to very high degrees of heat. Practice has enabled him to bring to perfection a capacity for supporting heat, which seems to be peculiar to persons engaged in the occupation of baking. Tillet gives an account of three girls, servants to a baker, who would remain in an oven heated to a very high temperature, while they swept it, laid the wood, and set the loaves for baking, taking no other precaution than that of keeping the door open. He has ascertained that they remained fourteen or fifteen minutes in the oven, when it was heated to 270° Fahrenheit, ten minutes at 279°, and fifteen minutes at 364°. Thus they supported a degree of heat 67° above that of boiling water, and 170° above that of the human body. Duhamel, Bankes, Solander, and others, have shown by experiments made upon themselves that man may support for some time, a temperature exceeding the natural heat by 174°. On Tuesday last, M. Martinez, the fire-proof man, exhibited his experiments before a vast concourse of spectators. To obviate all suspicion, an oven was heated in the middle of one of the grass-plots in the garden of Tivoli. At twenty-two minutes after eight, M. Martinez entered the oven; the thermometer, which was left in it eleven minutes, indicating 338° Fahrenheit. He remained in the oven fourteen minutes; his pulse, which was at 76 when he entered, beat 130 strokes in a minute when he came out.

Second experiment.—At two minutes before nine, his pulse was at 85; he again entered the oven, and remained seven minutes, the thermometer being at 285° Fahrenheit. The crowd of spectators who rushed forward to see him, when he came out, prevented the exact ascertainment of the state of his pulse, but it was less frequent than at the end of the first experiment.

Third experiment.—At nine minutes past nine, M. Martinez was placed upon a plank, surrounded with candles, and introduced into the oven, the door of which was then closed. He remained in it three minutes. On coming out his face was of a violet colour, but he hummed a tune with great apparent indifference, and plunged himself into a bath of cold water. Before the immersion, his pulse beat 144 strokes in a minute.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet Surgeon R. T. A. Levinge to the *President*, for three months' course at the Royal City of Dublin Hospital. Staff Surgeon H. Clift to the *Hawke* on recommissioning.

The undermentioned Surgeons have been promoted to the rank of Staff Surgeon in His Majesty's Fleet:—Patrick William MacVean (dated May 15th, 1903); Matthew Livingston Mitchell Vaudin and William Handford Thomson (dated May 13th, 1904); Ernest Stewart Reid (dated Nov. 10th, 1904); and Francis Frederick Lobb, Charles Clarke Macmillan, D.S.O., and James George Watt (dated May 23rd, 1906).

ROYAL ARMY MEDICAL CORPS.

Lieutenant-Colonel Edward North to be Colonel, vice W. E. Saunders, C.B., deceased (dated July 18th, 1906).

The undermentioned Majors to be Lieutenant-Colonels (dated July 28th, 1906):—Charles H. Burtchaell, John J. Gerrard, John S. Davidson, James Will, James Fallon, John V. Salvage, Arthur R. Aldridge, Joseph Fayrer, Charles J. Macdonald, Charles J. W. Tatham, Thomas H. F. Clarkson, Cathcart Garner, Robert W. Wright, Edwin Eckersley, Reginald J. O. Cottell, Daniel Hennessy, David M. Saunders, Denis M. O'Callaghan, Michael J. Whitty, James F. Donegan, John Donaldson, Hugh B. Mathias, D.S.O., George H. Barefoot, Foster R. Newland, Reginald J. Windle, John J. Russell, George Scott, Andrew Hosie, George F. H. Marks, Ralph Holyoake, Thomas Du B. Whaite, Henry T. Knaggs, Ferdinand S. Le Quesne, V.C., Robert H. Penton, D.S.O., Willington S. Dowman, and Albert L. F. Bate.

The undermentioned Majors are placed on retired pay (dated July 28th, 1906):—James Moir, Henry A. Cummins, C.M.G., George Bent, Edward S. Marder, Charles W. Allport, Thomas Browning, Robert N. Buist, and William J. Trotter.

The undermentioned Captains to be Majors:—John P. Silver (dated July 28th, 1906); Stephen W. Sweetnam (dated July 28th, 1906); William S. Harrison (dated July 29th, 1906); and Harry A. L. Howell (dated July 29th, 1906).

ARMY MEDICAL RESERVE OF OFFICERS.

Surgeon-Captain Eustace M. Callender to be Surgeon-Major (dated July 25th, 1906). Surgeon-Lieutenant Montague S. W. Gunning to be Surgeon-Captain (dated July 24th, 1906). Surgeon-Captain Arthur H. L. Stewart, having resigned his commission in the Imperial Yeomanry, ceases to belong to the Army Medical Reserve of Officers.

VOLUNTEER CORPS.

Royal Engineers (Volunteers): 1st Newcastle-on-Tyne: Surgeon-Captain H. H. Gourley resigns his commission (dated August 4th, 1906).

Rifle: 7th Volunteer Battalion the Royal Scots (Lothian Regiment): Surgeon Lieutenant-Colonel J. B. Ronaldson is borne as Supernumerary whilst holding the appointment of Brigade-Surgeon-Lieutenant-Colonel, Senior Medical Officer, 2nd Lothian Volunteer Infantry Brigade (dated July 1st, 1906). 1st Volunteer Battalion the East Yorkshire Regiment: Supernumerary Surgeon-Captain H. G. Falkner to be Surgeon-Major, remaining Supernumerary (dated August 4th, 1906). 2nd Volunteer Battalion the Royal Scots Fusiliers: Eric Dalrymple Gairdner to be Surgeon-Lieutenant (dated July 15th, 1906). 2nd Volunteer Battalion the Gordon Highlanders: Surgeon-Lieutenant G. P. Craver resigns his commission (dated August 4th, 1906).

diathesis," by which we presume is meant hereditary predisposition to insanity—a very small proportion indeed. In the large proportion of 56 the cause of the insanity was unknown. The forms of insanity appear from the table to have been the usual ones; general paralysis occurred in the low proportion of 12 of the 230 admissions. The deaths numbered 96, giving a percentage of 12·22 on the average number resident. Necropsies were obtained in the low proportion of 59 per cent. of the deaths; all cases being examined where no objection is made by the friends, the inference is that the latter object more commonly than is usual. 21·9 per cent. of the deaths—a high proportion—were due to tuberculous disease, a condition of things associated with the overcrowding referred to above. Four inquests were held during the year, two of which are of interest; in one the patient's death was ascribed to her having taken floor polish and in the other the verdict was "obstruction of the bowels caused by eating human hair." The report of the Commissioners in Lunacy, beyond a reference to the overcrowding which exists, contains nothing particularly noteworthy.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

FOR the third time in its history the British Association for the Advancement of Science held its meeting in York, and the proceedings were commenced on August 2nd with the delivery of the presidential address by Professor E. RAY LANKESTER, in which he gave an outline of the advancement of science in the past 25 years. In the course of his remarks Professor Lankester said that the meeting this year possessed an added interest from the facts that the first meeting of the association was held in York just 75 years ago and that its jubilee was celebrated at York in 1881 under the presidency of Sir John Lubbock (now Lord Avebury). Professor Ray Lankester closed his address with a strong appeal to the public to take a greater interest in the work of scientific research, and expressed the view that the organisation and finance of the research army should be the care of the State.

As is usually the case the meeting was divided into quite a large number of sections, and we can only attempt to review a few of the papers with a medical bearing.

Professor FRANCIS GOTCH presided in the section of Physiology, and he addressed his audience on the aims and methods of physiology. At the outset he referred to certain wide issues which were involved in the statement of the late Sir John Burdon Sanderson that the business of the physiologist was "to acquire an exact knowledge of the chemical and physical processes of animal life." The limitation of physiology to ascertainable characters of a chemical and physical type did not commend itself to certain physiologists, physicists, and chemists who had revived under the term "neovitalism" the vitalistic conceptions of older writers. They denied that physiological phenomena could ever be adequately described in terms of physics and chemistry. What possible justification, asked Professor Gotch, was there for branding as hopeless all further physical and chemical investigations of certain aspects of certain phenomena by attributing these to vital directive forces? The introduction of vitalism or biotic energy as a fictitious causative explanation was so opposed, he held, to the spirit and the progress of science that we might safely predict the complete abandonment of this position at a comparatively early date. At any rate, the recent history of physiological progress showed that investigations confined to the study of physical and chemical processes had been the one fruitful source of physiological knowledge. Professor Gotch gave as instances the splendid work of Emil Fischer on the nature and constitution of carbohydrates and quite recently of proteids.

The presidential address in the Chemistry section was delivered by Professor WYNDHAM DUNSTAN, who took for his subject, Some Imperial Aspects of Applied Chemistry. He pointed out the intimate connexion of chemical science with the problems that await solution in connexion with the utilisation of the raw materials and economic products of our colonies. The British manufacturer, he said, is in need of increased and better supplies of the raw material on which his industrial activity depends, and there were vast resources in our colonies which could only be developed by properly directed scientific investigation. In the course of his address Professor Dunstan gave an interesting account of the indiarubber industry, and added that chemists may confidently predict that before the British Association again meets at York the synthetic production of rubber will be a fully-accomplished fact.

An interesting discussion on Radio-activity was opened by the Hon. R. J. STRUTT in the Mathematical and Physical Science section, who dealt with the view that there might be enough radium in the earth to account for its internal heat. He had been led to the conclusion that there was much more radium in rocks than would be needed to maintain the earth's internal heat if the earth were constituted of rock throughout. From this he concluded that the interior of the globe does not contain radium.—Sir WILLIAM CROOKES expressed the idea that radium compressed and locked up in a rock had not much opportunity for heat emission.—Sir WILLIAM RAMSAY dissented from this view as his experiments had led him to exactly opposite conclusions. If the earth was a vast meteorite with a core and slag for crust they would know, he said, the amount of radium in it by testing meteorites, but Mr. STRUTT pointed out that meteorites did not contain radium.

There were some interesting papers communicated to the Physiological section on Sleep and Rest. Dr. THEODORE DYKE ACLAND pointed out the necessity of sleep or rest, especially for young and growing persons. He said that insufficient sleep diminished the power of resistance in the individual and rendered the young more liable to contract preventable disease.—Professor C. F. SHERRINGTON said that it was difficult to formulate any reliable theory as to the amount of sleep really required, and what was wanted was more data on these points, especially in regard to children and the boys in public schools.—Dr. C. S. MYERS said that he found that his memory grew in proportion to the number of hours of sleep that he took.

In the Chemistry section Mr. THOMAS JAMIESON read an instructive paper on the Utilisation of Nitrogen in Air by Plants. He had found that certain plants were endowed with a distinct organ which was admirably situated and especially adapted for the absorption of nitrogen. This organ was at first destitute of nitrogen; it became gradually gorged with nitrogenous matter, and then disgorged the matter into the plant generally. The results were supported by a very interesting series of experiments.—A paper on a similar subject was read by Professor W. B. BOTTOMLEY who referred to the fact that sprinkling urine on the floor of the greenhouse caused a more luxurious growth of orchids. The ammonia liberated from urine was absorbed along with the aqueous vapour condensed by the velamen cells, the absorption of the ammonia being accomplished by the nitrifying action of bacteria.—Dr. GEORGE REID also referred to the nitrifying action of organisms in an interesting paper on the treatment of sewage in shallow filters containing fine particles. He concluded that, given fine particles and good distribution, sewage filters may be constructed much shallower than hitherto; and also that, if a sewage by reason of its strength should prove to be exceptionably resistant to treatment, more will be effected by increasing the area than by deepening the filter.—An interesting paper was read in Section G by Mr. A. J. MARTIN, M.I.C.E., on a general supply of gas for light, heat, and power production. The inauguration of a general supply of cheap gas would, he said, have far-reaching consequences. The smoke nuisance, with its appalling death roll, would be done away with, and the annoyance and damage to property from smoky fogs would be brought to an end. A cheap and abundant supply of sulphate of ammonia would come to the aid of our distressed agricultural interests. The most far-reaching effect of cheap gas, however, would probably be in stimulating the establishment of manufacturing plants in rural districts, thus helping to relieve the congestion in overcrowded towns. No single factor, he pointed out, had played so great a part in determining the distribution of industries as the existence of natural sources of power, and with gas at the prices at which it could be supplied from the collieries, gas power would be even cheaper than water power.

series of very curious mistakes. I defeated him with great slaughter and I still preserve his autograph letter admitting his mistakes. In 1871 Dr. Spencer Cobbold, F.R.S., the great *helminthologist*, attacked me with enthusiastic impetuosity as an enemy of the human race trying to disseminate intestinal diseases by sewage irrigation. But I had anticipated such an attack and eventually he signed judgment against himself, as may be found in the fourth report of the committee of the British Association on the "Treatment and Utilisation of Sewage," at pp 188, 189 of the forty-first report of the Association.

This is the story. On my Romford experimental sewage farm I had taken a calf the parents of which had been fed on sewage grown produce since before his conception, as soon as he could be taken from his mother (which was still being fed on sewage-grown produce), devoted him to science, and kept him in a roomy box for 22 months. In very wet or very cold weather he received at times a little hay or straw, merely enough dry food to keep him in health; otherwise he was fed exclusively on sewage-grown produce; and my object being to give all entozoal individuals a fair chance, he was given only the *rakings* from the Italian grass after the swaths had been carted off, and the outside leaves of cabbages, mangold, and sugar beet, or these roots when no grass or leaves were available. On the day appointed for the sacrifice Professor Marshall, F.R.S., the great surgeon, and Professor W. H. Corfield, both of University College, and some more of my colleagues on the committee (I think Dr. J. H. Gilbert, F.R.S., Dr. A. Voelcker, F.R.S., and Dr. A. W. Williamson, F.R.S.) were present and Dr. Cobbold himself was in special charge of the necropsy. To assist him and Professor Marshall and Professor Corfield I had present two veterinary surgeons and two butchers and the dissection lasted all of a long summer day.

The following are the principal passages in Dr. Cobbold's report: "...... I have to report the perfect freedom of that animal from internal parasites of any kind. I attribute this marked negative result to the following circumstances. First, the animal did not graze on the farm but was fed exclusively upon vegetable products cut and carried from the land. Secondly, the porous nature of the soil and sub-soil alike would rapidly carry off the sewage and thus insure the passage of parasitic germs into the soil itself. Thirdly, I noticed on the irrigated portions of the farm a remarkable absence of those molluscan and insect forms of life which frequently play the part of intermediary bearers. ...... Fifthly, the flaky vegetable tufts collected by me from the sides of the furrows occupied by sewage currents consisted chiefly of *Batrachospermum moniliforme*, in the filaments of which were numerous active nematodes, but no ova of any true entozoon. ...... As some guarantee for the efficient manner in which the carcass of the ox was examined I may mention that the superficial muscles with their associated areolar and aponeurotic coverings were particularly investigated, portions of certain muscles such as the scaleni and sterno maxillaris being dissected through and through. All the viscera were likewise scrutinised, especially the brain, lungs, liver, bladder, kidneys, paunch, reed, cæcum, and other natural divisions of the intestinal canal."

Remarks by the committee.—"...... Those members of the committee who were present and examined it"—the ox—"with Dr. Cobbold concur in his statement as to its perfect '*freedom from internal parasites of all kinds*'"—the italics are the committee's. "They especially draw attention (1) to the fact that on this farm there is 'a remarkable absence of those molluscan and insect forms of life which *frequently* play the part of intermediary bearers' to entozoal larvæ; and (2) to the composition of the 'flaky vegetable tufts' collected from the sides of the carriers. *These* contained 'numerous active free nematodes but no ova of any true entozoon.' It appears, then, that as far as this one case goes (and it is certainly as conclusive as a *single* case could possibly be), there is no evidence that entozoal forms of life are to be found on the farm at all in any stage of their existence or in the flesh of an animal fed exclusively for 22 months on sewaged produce grown on the farm."

The veterinary surgeons and the butchers said that they had never seen any ox so entirely healthy in every way, with no trace even of old disease, and they and everyone present asked me how I accounted for such a phenomenon. I replied that my explanation was very simple—namely, that the ox was specially watered from the house well and not from a horse pond. What I myself thought was just remotely possible was that ova or *hydatids* of T. mediocanellata might have been discovered, for it was probable that many thousands of these ova must have come on to the farm in the 22 months, but, as I believe, not in a condition of vitality. Their absence and that of all other *forms* of entozoal life in the ox was, I venture to think, the triumph of scientific sewage irrigation, so admirably summed up in Frankland's three words, "intermittent downward filtration," which no doubt carried them down into the soil.

I served on the above committee for seven years and I regret to say that all my colleagues have, alas, gone over to the majority except Dr. W. Odling, F.R.S. Sir John Lubbock, F.R.S. (now Lord Avebury), is happily also living, but though nominally a member of the committee, he only acted as treasurer, as our labours were outside his ordinary scientific work and were without the poetic charm of his researches. But the work of the committee was of such great scientific and practical importance that I feel it to be a duty to the country, to the association, and to my much lamented colleagues, with whom I worked so long and with such pleasure, to exhume their forgotten but invaluable work, and I feel sure that both Dr. Odling and Lord Avebury will warmly support that view.

I leave to the medical profession the questions: 1. Whether the presence in an appendix of any entozoal ova can, and must, produce appendicitis. 2. Whether a few drops of thymol, which is a mild antiseptic, taken by the mouth, can find their way—while still antiseptic—to the appendix. 3. Whether having done so, and having destroyed the ova, these will remain for ever harmless. 4. Whether by the microscope an experienced observer can distinguish, for certain, between the ova of the T. trygocephalus and, say, of the T. echinococcus of the dog, so frequently present in stable manure used in market gardens.

I am, Sirs, your obedient servant,

W. HOPE,
Colonel.

Parson's Green, July 24th, 1906.

SUGGESTIONS FOR THE FUTURE OF CONSUMPTIVE PATIENTS OF THE WORKING CLASSES.

To the Editors of THE LANCET.

SIRS,—It is well that more thoughtful attention is being given to the question of the future occupation of consumptive patients, drawn from the working classes, who have been under treatment in chest hospitals or open-air sanatoriums. All those who have any real knowledge of this class of patient are fully alive to the unpractical advice often meted out to these people. Resident medical officers and others in charge of such institutions are bound to be confronted, on discharging their patients, with the question, "What work am I to do?" and to answer such a question and to offer advice worth the having as to a future occupation present what appear to be almost insuperable difficulties in many cases.

Only to-day I was led to advise a skilled worker *to return to his* workshop and to a situation which had been kept open for him, as on his own showing the conditions were not absolutely undesirable, and he himself was penniless and had no means of obtaining equally remunerative employment in the open air or under more favourable *conditions*. The patient was surprised, as he had on more than one occasion been told of the excessive danger to himself of resuming his *old calling* and been urged to seek light open-air work. It is essential that members of the medical profession should avoid, so far as possible, this flat contradiction of each other if any real progress is to ensue, and therefore we welcome as a stimulus to thoughtful consideration of a problem which is daily forcing itself upon all those who have any share in teaching the working-class consumptives the article in THE LANCET of July 28th, p. 217, by Dr. M. S. Paterson and Dr. F. C. Shrubsall. The routine advice so long adopted both in hospital and general practice, "get open-air work," is almost useless. The difficulties besetting the healthy in search of such occupations are too well known to be repeated and much misery and suffering to themselves and their families have resulted from even genuine seekers after "*outdoor*" employments. We run the risk of creating loafers of the very worst type and swelling the ranks of the unemployed and unemployable by holding up "open-air work" as a *sine quâ non* to men who eventually become content to be

THE MEAT OF THE PEOPLE.

To the Editors of THE LANCET.

SIRS,—My attention has been directed to a letter appearing *in THE LANCET of July 28th, signed* "Peripateticus," in which the writer offers the opinion that New Zealand frozen mutton is neither so nutritious nor so digestible as English meat. Your correspondent, however, submits no proof in support of this opinion. Consequently his statement can have little weight. I desire, however, to point out that the relative merits of New Zealand and English mutton have frequently been considered by those closely concerned in the question. Among other tests to determine this I would mention those made a few years ago by the *Hospital* experts when, after exhaustive experiments with New Zealand frozen mutton and Scotch mutton, these gentlemen reported that "the New Zealand meat, weight for weight, has a greater amount *of food constituents if the* fat be taken into account" and that "the digestibility of the meat is all important from the invalid's standpoint, and *remembering that New Zealand meat is very commonly* indeed used for the patients' diets, it is very reassuring to find that the *freezing process* does not *to* any appreciable extent render it less easy of assimilation, or constitute a drawback to its use for persons of feeble digestive *powers.*" I inclose herewith a *report of* the tests referred to, from which you will see that the assertion that New *Zealand frozen mutton is neither so nutritious nor so* digestible as English mutton is completely refuted.

I am particularly gratified to note the kind reference of "Peripateticus" to the watchfulness and care with which the whole process of preparation of meat for the English market *is carried out in New Zealand. That "there is no* question of suspicion as to cleanliness or purity or careless inspection in the colony" is a testimonial that at the present moment, when consumers are so doubtful on these special points, is doubly welcome. With the substitution and sale *of New Zealand meat as English the New Zealand producer* has no sympathy. He would prefer that the product of the colony was altogether sold to consumers here on its merits and at its proper market value. He considers the sale of New Zealand meat as English at English price a fraud upon consumers that should be *stopped by law.*

I am, Sirs, yours faithfully,

W. P. REEVES,

High Commissioner for New Zealand.

Victoria street, London, S.W., August 1st, 1906.

THE PROMOTION OF SCIENTIFIC RESEARCH.

To the Editors of THE LANCET.

SIRS,—In view of the appeal made in the *presidential* address at the meeting of the British Association yesterday for funds for reseach in relation to disease, I shall feel obliged if you will permit me to make some observations upon certain *aspects of my scheme for the promotion* of *scientific research* which have reference to the endowment of research and which may be readily overlooked on a cursory consideration of it. I made no allusion to these aspects of the scheme in my letter appearing in THE LANCET of Sept. 30th last, which refers to a leading article upon the scheme in a *previous* issue of your journal. The scheme, I may remind you, defines conditions under which public moneys may be allocated to grants for discoveries of prescribed descriptions, and it formulates a course of procedure whereby the fulfilment of such conditions may be ascertained. The procedure is, as you will have observed, largely analogous to patent law procedure. No provision in the scheme restricts an applicant's or intending applicant's power to assign a grant to which he may become entitled. Any such applicant or intending applicant may *therefore assign* a part *or* the whole of a prospective grant for a valuable consideration in a manner somewhat analogous to that in which an inventor of a patentable invention may dispose of a share or the whole of his patent rights in such invention.

It will be obvious that where researches directed to the *making of discoveries, for which* the grants may be obtained, are maintained *out of* any endowment fund, those having control of such fund could make it obligatory upon any research worker receiving remuneration, or being otherwise assisted out of such fund, to assign for the purposes of the fund a part or the whole *of any prospective grant* which such worker *might* succeed *in obtaining.* Such an obligation might be equitably imposed where coöperative research work, maintained by any institution, may issue in results for which grants could be obtained.

Public moneys may be allocated in conformity with the *principles of the scheme to grants for discoveries* which elucidate the nature or causation of, or which diminish the mortality due to, a specified disease from which the mortality is great. The scheme provides for the periodical investigation of discoveries forming the subject matters of *application for the grants*, the *maximum amounts* of which are to be prescribed as *provided* by Clauses 22, 29, and 41 of the scheme. If the disease be of so widely prevalent and terrible a nature as, say, cancer the amount of such grants may be justifiably large. And it will *therefore* be seen that if by means of an endowment fund, such as, for example, the Imperial Cancer Research Fund, discoveries are made of the description *referred to*, the scheme, if it were in operation, might be the means of adding materially to the amount of such fund. State *aid, it will thus be* apparent, *might* be obtained indirectly under the provisions of the scheme for endowed institutions, without especially favouring any individual, or class of individuals, applying for the grants. I therefore hope that when the scheme is more fully understood support may be gained for it as well *from* endowed institutions as from those who are desirous that provision be made for research independently of such institutions.

I am, Sirs, yours faithfully,

WALTER B. PRIEST.

Verulam buildings, Gray's Inn, W.C., August 2nd, 1906.

APPENDICITIS AND PROFESSOR BLANCHARD.

To the Editors of THE LANCET.

SIRS,—Professor Blanchard of Paris is stated to have announced that the above dangerous *malady is caused by* the ova of tænia trygocephalus and of two others which he does not name, and he says that he and Metchnikoff found *these ova in each of a considerable* number of appendices which they examined. Blanchard is also stated to speak of these ova as "*parasites," a word not applicable* to the ovum, which could only become the perfected parasite by passing through the alternate generation of *hydatid* in an intermediary bearer. Unfortunately I have no access to Blanchard's *ipsissima verba* and am obliged *to* accept the version of the daily press, and *I may* be misled.

I felt it to be my duty to study that singular page of natural history "helminthology" some 35 or 40 years ago, when *labouring so* hard to get sewage used as a manure instead of as a poison. In this I always had *your whole* hearted support, and with your commissioner, Dr. Stallard, I had frequent communication in those old days, but it is *now*, I suppose, 30 years since I found *myself* writing to THE LANCET. I come out of my shell now because *Blanchard, having abolished* appendicitis without an operation by a *few drops* of thymol, is said to state as a fact—but without apparently the *slightest* attempt at investigation—that these ova are due to the chemically treated sewage of Paris and London used to force vegetables in market gardens. Unfortunately for Blanchard, and still more unfortunately for London, none of its sewage is now con*verted* into vegetables, the sludge being carried by a large *fleet* at huge cost *far out to sea to* poison fish, and the liquid *being still* used for the *pollution of* the Thames and as poison for its fish and riverside population.

Since 1862 I have fought many *battles* in favour of the use of sewage as manure instead of as a poison, and yet in 1906 here comes Professor Blanchard *with a new* and absolutely groundless libel on what I used to describe as the liquor humanitatis. In 1865 the great *Liebig* attacked me in a series of letters in the *Times*, on chemical grounds, under a

THE INFECTIOUSNESS OF TYPHOID FEVER.

To the Editors of THE LANCET.

SIRS,—I hope you will excuse my boldness in venturing to demur to your dictum in THE LANCET of July 28th, p. 245, on the infectiousness of typhoid fever. I do so in the interests of public health, which must suffer very seriously if the weight of your great authority is thrown in the scale when so momentous a question as to the danger of infection from a particular disease comes to be decided. This is not merely a theoretical point but one of the greatest importance in proper sanitary administration all over the country. Let me appeal in the first place to pathology. Surely typhoid fever is as much a disease of the blood as typhus fever or any of the other exanthemata. The skin, the lungs, the spleen, the liver, and the pharynx come to be affected and not merely the glands of the small intestine. In the case of the pharynx particularly the bacillus typhosus has been found both in the living and dead subjects; and if so, why should it not be carried in the sputa and expectorated as spray in the breath just as tubercle bacillus is carried from person to person? In the second place, appealing to experience, did not the American commission on the diseases of the Cuban campaign find irrefragable proof of infection by personal contact? I have been constantly seeing cases of typhoid fever for nearly 50 years and have over and over again met with examples of personal infection. Two of my assistants have fallen victims to the complaint in attending patients, and in our hospital here three nurses have been so infected. In my own family one of my assistants infected my own children; and my son, by the stupid bungling of the authorities who placed the enteric fever cases into immediate proximity of the surgical lines in the hospital where he was working, had the trouble so badly as to just escape with his life.

Now, Sirs, I can well believe that this evidence does not completely convince the advocates of water-borne typhoid fever and that form of infection alone. But if there be merely room for the smallest doubt on the point surely it is not far short of criminal not to take every precaution against the spread of the disease by *every* possible channel of *any* kind. As a medical officer of health I at least would feel guilty in all such cases if I did not attempt to shut the door against every imaginable source of spreading disease.

As to providing opportunities to students to become acquainted clinically with typhoid fever, it must surely be in the eyes of those who do not believe in personal infection of vastly more importance that the raw practitioner should be able to diagnose properly such diseases as small-pox and typhus fever, which he can only become acquainted with in isolation hospitals. If, as cannot be gainsaid, he ought to study these latter complaints by the bedside then he must go where such diseases can be seen, and while so occupied surely he may take advantage of the opportunity to make himself acquainted clinically with typhoid fever as well. On every ground, then, let us exclude this latter disease from general hospitals and let me add—parenthetically—phthisis as well.

I am, Sirs, yours faithfully,
WILLIAM BRUCE, M.D. Aberd.,
Medical Officer of Health of Ross and Cromarty.
Dingwall, July 30th, 1906.

DEATH FROM OVERLYING.

To the Editors of THE LANCET.

SIRS,—May I, through the medium of your columns, draw attention to a case of death from overlying in which the external post-mortem appearances were unusually definite. I was called early one Sunday morning to see a child 14 days old who was found dead in bed by its mother. The history briefly was this. After visiting several public-houses the mother, who carried her baby with her, was brought home in a drunken condition by friends. They undressed her and put her to bed and placed the baby close to her right side. This was between the hours of 11 and 12 at night. When she awoke in the early hours of the morning she found her baby dead.

On examining the body at 7.30 on Sunday morning I found rigor mortis well marked. The face was of a uniform dusky hue, and there were large patches of the same colour on the chest, abdomen, and on the front of both legs. The right forearm was flexed on the arm and the thumb was clenched by the fingers. The right thigh was flexed on the abdomen, and the big toe was strongly extended at the metatarso-phalangeal joint. The limbs on the left side presented nothing noticeable. The body was removed to the public mortuary and a post-mortem examination made at 3.30 P.M. on the same day. The appearances were the same as at the earlier hour, save that rigor mortis was not so marked and that post-mortem stains were forming at dependent parts. The discolouration of the skin had not altered in position. Pressure with the finger on the cheek did not cause blanching of the skin. The lips were purple. A bloody froth which was not noticeable early in the day had now exuded from both nostrils.

The post-mortem appearances in death from overlying are extremely unsatisfactory and the medical man can often find nothing on which to base an opinion. In this case, however, with the clear history of a healthy infant being placed near its drunken mother, the post-mortem appearances were pronounced. Exudation of a bloody froth from both nostrils is not mentioned as a sign in either of the two text-books I have at hand (Dixon Mann's and Aubrey Husband's). Dixon Mann writes that the mucous membrane of the larynx and trachea is sometimes found injected and may be covered with frothy mucus, possibly blood-stained (Forensic Medicine, p. 226). He quotes Lambert, who examined the dead bodies of several children who were killed from compression of the chest in a stampede from a public building and in a majority of these Lambert noticed froth surrounding the mouth and nostrils. Aubrey Husband writes that the presence of froth about the mouth is not constant and is a common occurrence in those dying from natural causes.[1] It is worth noticing that although the child's nose and mouth presented nothing remarkable at 7.30 A.M. yet at 3.30 in the afternoon a bloody froth extended from both nostrils almost to the chin. General convulsion of all the muscles of the body is one of the stages of asphyxia. The reason why it was noticeable only on the right side may have been because the child lying close by its mother had the left half of its body fixed down by her weight whilst its right was free to contort and twist. The discolouration of the face was a noticeable feature of the case. It resembled the face of a child deeply cyanosed from congenital heart disease, the "morbus cæruleus." The cheek blanched under pressure of the finger but the deep colour gradually returned, and when the body was again examined in the afternoon the face was completely suffused. The body had lain several hours in the mortuary in the dorsal position and post-mortem stains were visible in the dependent parts, but the colour of the face persisted. Turgescence due to throttling passes off, as a rule, shortly after death.

I am, Sirs, yours faithfully,
JOSEPH A. W. PEREIRA, M.D. Brux.
Exeter, August 3rd, 1906.

SPASMUS NUTANS.

To the Editors of THE LANCET.

SIRS,—I have just read with interest the article in THE LANCET of July 28th by Dr. G. F. Still on "Head-Nodding with Nystagmus in Infancy." About a year ago a case came under my notice in hospital which differs in some respects from the cases just published by Dr. Still. I must apologise for not giving a definite history, as I have no notes of it and I have to rely on my memory entirely. It was in a girl, aged five years, who was admitted to hospital for the removal of her tonsils and adenoids. Although she did not show any active signs of rickets she was wasted and ill-nourished and was for that reason kept in hospital for a fortnight after the operation, and it was during the first week that the head-rolling was observed, it gradually lessening under the careful treatment given in hospital.

The exciting cause, however, I feel sure was the presence of pediculi on the scalp. On admission the head was in a terrible state, and it was only after it was cleansed and she was placed on nourishing diet that the cure of the spasmus nutans was accomplished. In addition to the head-nodding she exhibited marked symptoms of nystagmus, but I am unable now to state if one eye was more affected than the other—a point so much emphasised by Dr. Still. She supported by their wives. Of such results we cannot be proud.

---

[1] Handbook of Forensic Medicine, p. 101.

On the other hand, we must not lose sight of the many difficulties which lie before the consumptive who has to return to indoor occupations, especially if this follows immediately on discharge from open-air hospitals or sanatoriums. Our own experience tells us how absolutely distasteful and opposed to the highest work of mind or body is the vitiated atmosphere of a crowded factory or workshop, especially after a sojourn in the pure air of the country, where the contrast is so marked. Even if the means for thorough ventilation are provided and opportunities are given to our ex-patients to disseminate the teaching imparted while under medical treatment in our sanatoriums, such apostles of hygienic conditions of life lay themselves open to more or less serious trouble and are voted an unbounded nuisance. To use a spitting flask is to openly court disaster and to ask for open windows brings suspicion in its train. Small wonder, then, that many of them under such depressing and disheartening conditions give up their newly acquired habits and therefore relapse.

To take one instance out of many that could be brought forward, school teachers, who naturally realise the absolute necessity of hygiene, tell us that the attitude of the parents makes it impossible to ventilate schoolrooms and therefore the majority of those in the scholastic profession who have been unfortunate enough to contract the disease resolve at once, when they realise their own needs and the almost impossibility of any real fulfilment of hygienic conditions, to seek some other employment.

Dr. F. W. Burton-Fanning has been pointing out for some considerable period that every ex-patient need not necessarily seek "outdoor employment." He says: "In many cases it is far more important to stipulate that the work involve no fatigue or physical strain, and if the employment involve restriction of fresh air this must be sought more thoroughly during leisure hours." The medical staff of this hospital (I speak for the time of my own connexion with it) has from time to time been pointing out that the sweeping condemnation of all indoor work was absurd and that many of the patients would be doing themselves more harm than good by changing their occupation and giving up their position as skilled workers for the chance of outdoor employment, which was at the best of times remote. It would seem a wiser expenditure of energy to concentrate our attention on the conditions under which our patients have to return to work, without at the moment having regard to the nature of the work itself. Nor is it easy to obtain an adequate idea of these conditions from the patients and the ideal advice as to their suitability would seem to be that founded on a personal investigation. Nor can we ignore the fact that some patients continue to do well under the most adverse conditions. We have an ex-patient who has been in the hospital four times during the past 12 years. He worked in an underground bakehouse and informs us that he rarely does less than 12 hours a day. He comes into the hospital for a short stay and then returns to work again, keeping quite well in the intervals, despite the fact that he was assured by the physicians of a leading chest hospital 12 years ago that if he did not get open-air work he could not live. Needless to say, he does not continue such an occupation at our suggestion, but the case is a remarkable example of the resisting power of some patients, even in the most unfavourable circumstances.

The article in THE LANCET of July 28th does not deal with women workers. The majority of our women patients are domestic servants of one class or another. Once let it be known that they have been under treatment and there are few, if any, situations open to them, and of these a great many prove absolutely unsuitable when the long hours, heavy work, and unsatisfactory sleeping accommodation are taken into account. To advise such persons to attempt to carry out the treatment they have learned is a counsel of perfection which is quite unattainable. On the other hand, what is to be the alternative? The usual alternatives offered to men mentioned by Dr. Paterson and Dr. Shrubsall—viz., "going to sea" and "emigration"—one had almost thought were obsolete. To recommend an ex patient to seek a steward's or purser's berth on board ship would never be seriously entertained by anyone who knew anything of the disease on the one hand or of the conditions of life on board ship on the other. The idea that "emigration" is a panacea for all the ills that our patients are heir to has been dispelled by the experience of emigrants themselves. As regards work on farms or in gardens it is only necessary to point out that very few employers in the country districts can afford to be philanthropists in these days and therefore they cannot give a living wage to men who hardly know how to handle a spade properly. We are, it seems to me, bound to admit that in nearly all the cases the best chances consist in returning to the old work with a new knowledge of how to grapple with the conditions under which that work is to be carried out.

If we can impress upon some of them the advisability of procuring work in the smaller towns in preference to the large cities, even at a less wage, if they can thereby spend their leisure hours more easily in the open country, we shall have attained something. Real work may be done to supplement the educative system of our hospitals and sanatoriums by seeking to induce employers of labour to improve the hygienic conditions of factory and workshop. And even in face of the many difficulties which beset the whole subject we must still hope that the general public will become more enlightened, so that when our patients return to their old occupations they will meet with efforts on all sides to help them to continue their more hygienic mode of life instead of, as is so often the case, having real obstacles put in their way. I am, Sirs, yours faithfully,

W. G. KINTON,

Resident Medical Officer, Mount Vernon Hospital for Consumption and Diseases of the Chest, Northwood, Middlesex.

August 1st, 1906.

To the Editors of THE LANCET.

SIRS,—I was very glad to read the article by Dr. M. S. Paterson and Dr. F. C. Shrubsall which appeared in THE LANCET of July 28th under the above heading. Little good is likely to come of recommending ex-sanatorium patients to seek work in country districts, especially if such have to leave the ranks of skilled to swell the ever-increasing ranks of unskilled labour.

Surely the remedy lies in so improving the sanitary condition of our factories and workshops that the skilled workman may go back to his job with a fair chance of maintaining that improvement in health gained by sanatorium treatment. I am aware that there are great difficulties to be overcome before such an ideal state of affairs can be brought about in this country. Nevertheless, such difficulties are not insuperable, and once overcome are likely to afford a more rational solution to a vexed problem than would be the finding of special unskilled occupation for skilled men.

The writers' remarks as to sea-going and emigration are, from a New Zealand standpoint, particularly opportune, especially as regards the latter. Few physicians when they glibly advise a consumptive working man to go to the colonies can realise the adverse conditions under which the unfortunate patient has to travel, especially if the weather be bad and the emigrants have to pass most of their time in cabins which under the best conditions are crowded and ill ventilated. What man would advise, knowing the true conditions, such a patient a purser's mate's job in a small cabin or the stuffiness of the steward's "glory hole"? Many and many consumptive patients have I seen who have arrived at New Zealand ports in varying stages of the disease with no friends to go to, with no knowledge of the country, and with very little money. I can call to mind many instances where within two or three months of arrival such unfortunate persons have been on the charitable aid rates of the colony. That patients should be sent out under such conditions is neither fair to themselves nor to the ratepayers at large. In New Zealand we are doing all that can be done towards stamping out the scourge of tuberculosis. Sanatoriums are being established in various parts of the colony by public subscription and Government subsidy, and though in New Zealand the consumption death-rate is only about half what it is in this country there are no special advantages of climate sufficient to compensate a poor consumptive for risking the disadvantages of a long voyage in search of a "cure" which can for the most part be obtained at his own door and within comparatively easy reach of those most intimately concerned in his welfare. Moreover, legislation exists and is likely to be more stringently enforced to prevent the indigent consumptive from landing on New Zealand's shores.—I am, Sirs, yours faithfully,

T. H. A. VALINTINE, D.P.H., M.R.C.S. Eng.,
L.R.C.P. Lond.,
Assistant Chief Health Officer of New Zealand.

Farnborough, Hants, July 30th, 1906.

THE INFECTIOUSNESS OF TYPHOID FEVER.

To the Editors of THE LANCET.

SIRS,—I hope you will excuse my boldness in venturing to demur to your dictum in THE LANCET of July 28th, p. 235, on the infectiousness of typhoid fever. I do so in the interests of public health, which must suffer very seriously if the weight of your great authority is thrown in the scale when so momentous a question as to the danger of infection from a particular disease comes to be decided. This is not merely a theoretical point but one of the greatest importance in proper sanitary administration all over the country. Let me appeal in the first place to pathology. Surely typhoid fever is as much a disease of the blood as typhus fever or any of the other exanthemata. The skin, the lungs, the spleen, the liver, and the pharynx come to be affected and not merely the glands of the small intestine. In the case of the pharynx particularly the bacillus typhosus has been found both in the living and dead subjects; and if so, why should it not be carried in the sputa and expectorated as spray in the breath just as tubercle bacillus is carried from person to person? In the second place, appealing to experience, did not the American commission on the diseases of the Cuban campaign find irrefragable proof of infection by personal contact? I have been constantly seeing cases of typhoid fever for nearly 50 years and have over and over again met with examples of personal infection. Two of my assistants have fallen victims to the complaint in attending patients, and in our hospital here three nurses have been so infected. In my own family one of my assistants infected my own children; and my son, by the stupid bungling of the authorities who placed the enteric fever cases into immediate proximity of the surgical lines in the hospital where he was working, had the trouble so badly as to just escape with his life.

Now, Sirs, I can well believe that this evidence does not completely convince the advocates of water-borne typhoid fever and that form of infection alone. But if there be merely room for the smallest doubt on the point surely it is not far short of criminal not to take every precaution against the spread of the disease by every possible channel of any kind. As a medical officer of health I at least would feel guilty in all such cases if I did not attempt to shut the door against every imaginable source of spreading disease.

As to providing opportunities to students to become acquainted clinically with typhoid fever, it must surely be in the eyes of those who do not believe in personal infection of vastly more importance that the raw practitioner should be able to diagnose properly such diseases as small-pox and typhus fever, which he can only become acquainted with in isolation hospitals. If, as cannot be gainsaid, he ought to study these latter complaints by the bedside then he must go where such diseases can be seen, and while so occupied surely he may take advantage of the opportunity to make himself acquainted clinically with typhoid fever as well. On every ground, then, let us exclude this latter disease from general hospitals and let me add—parenthetically—phthisis as well.

I am, Sirs, yours faithfully,
WILLIAM BRUCE, M.D. Aberd.,
Medical Officer of Health of Ross and Cromarty.
Dingwall, July 30th, 1906.

DEATH FROM OVERLYING.

To the Editors of THE LANCET.

SIRS,—May I, through the medium of your columns, draw attention to a case of death from overlying in which the external post-mortem appearances were unusually definite. I was called early one Sunday morning to see a child 14 days old who was found dead in bed by its mother. The history briefly was this. After visiting several public-houses the mother, who carried her baby with her, was brought home in a drunken condition by friends. They undressed her and put her to bed and placed the baby close to her right side. This was between the hours of 11 and 12 at night. When she awoke in the early hours of the morning she found her baby dead.

On examining the body at 7.30 on Sunday morning I found rigor mortis well marked. The face was of a uniform dusky hue, and there were large patches of the same colour on the chest, abdomen, and on the front of both legs. The right forearm was flexed on the arm and the thumb was clenched by the fingers. The right thigh was flexed on the abdomen, and the big toe was strongly extended at the metatarso-phalangeal joint. The limbs on the left side presented nothing noticeable. The body was removed to the public mortuary and a post-mortem examination made at 3.30 P.M. on the same day. The appearances were the same as at the earlier hour, save that rigor mortis was not so marked and that post-mortem stains were forming at dependent parts. The discolouration of the skin had not altered in position. Pressure with the finger on the cheek did not cause blanching of the skin. The lips were purple. A bloody froth which was not noticeable early in the day had now exuded from both nostrils.

The post-mortem appearances in death from overlying are extremely unsatisfactory and the medical man can often find nothing on which to base an opinion. In this case, however, with the clear history of a healthy infant being placed near its drunken mother, the post-mortem appearances were pronounced. Exudation of a bloody froth from both nostrils is not mentioned as a sign in either of the two text-books I have at hand (Dixon Mann's and Aubrey Husband's). Dixon Mann writes that the mucous membrane of the larynx and trachea is sometimes found injected and may be covered with frothy mucus, possibly blood-stained (Forensic Medicine, p. 226). He quotes Lambert, who examined the dead bodies of several children who were killed from compression of the chest in a stampede from a public building and in a majority of these Lambert noticed froth surrounding the mouth and nostrils. Aubrey Husband writes that the presence of froth about the mouth is not constant and is a common occurrence in those dying from natural causes.[1] It is worth noticing that although the child's nose and mouth presented nothing remarkable at 7.30 A.M. yet at 3.30 in the afternoon a bloody froth extended from both nostrils almost to the chin. General convulsion of all the muscles of the body is one of the stages of asphyxia. The reason why it was noticeable only on the right side may have been because the child lying close by its mother had the left half of its body fixed down by her weight whilst its right was free to contort and twist. The discolouration of the face was a noticeable feature of the case. It resembled the face of a child deeply cyanosed from congenital heart disease, the "morbus caeruleus." The cheek blanched under pressure of the finger but the deep colour gradually returned, and when the body was again examined in the afternoon the face was completely suffused. The body had lain several hours in the mortuary in the dorsal position and post-mortem stains were visible in the dependent parts, but the colour of the face persisted. Turgescence due to throttling passes off, as a rule, shortly after death.

I am, Sirs, yours faithfully,
JOSEPH A. W. PEREIRA, M.D. Brux.
Exeter, August 3rd, 1906.

SPASMUS NUTANS.

To the Editors of THE LANCET.

SIRS,—I have just read with interest the article in THE LANCET of July 28th by Dr. G. F. Still on "Head-Nodding with Nystagmus in Infancy." About a year ago a case came under my notice in hospital which differs in some respects from the cases just published by Dr. Still. I must apologise for not giving a definite history, as I have no notes of it and I have to rely on my memory entirely. It was in a girl, aged five years, who was admitted to hospital for the removal of her tonsils and adenoids. Although she did not show any active signs of rickets she was wasted and ill-nourished and was for that reason kept in hospital for a fortnight after the operation, and it was during the first week that the head-rolling was observed, it gradually lessening under the careful treatment given in hospital.

The exciting cause, however, I feel sure was the presence of pediculi on the scalp. On admission the head was in a terrible state, and it was only after it was cleansed and she was placed on nourishing diet that the cure of the spasmus nutans was accomplished. In addition to the head-nodding she exhibited marked symptoms of nystagmus, but I am unable now to state if one eye was more affected than the other—a point so much emphasised by Dr. Still. She also had a very bad internal strabismus in both eyes, for which she was wearing convex glasses.

---

[1] Handbook of Forensic Medicine, p. 161.

The case seems to me the more interesting now after reading Dr. Still's paper, as the age of the child does not tally with the ages of those reported and also I find no mention of the pediculus capitis as a cause of head-nodding. I may say that it was always when sitting up that she rolled her head, that the movement was from side to side, that the nods were quite 100 to the minute, and generally lasted for a period varying between one and two minutes, but that there was no regularity of time between the spasms.

I am, Sirs, yours faithfully,

North Kensington, W., August 1st, 1906. HAROLD MOWAT.

MEDICAL PRACTICE IN SOUTH AFRICA AND ITS COMPLICATIONS.

To the Editors of THE LANCET.

SIRS,—South Africa may be divided into two parts—the veld where there are no medical men and the towns where there are too many. One consequence of this unequal distribution of the profession is that the farmer on his "plaas" on the lonely illimitable veld has to treat most of the ailments of his household. He has a "pelikaan" for tooth extraction and his wife has her "apotheek"—a box full of the locally renowned Dutch medicines,[1] such as Haarlem oil, Spanish fly, Hofman's drops, &c., but these have of late been supplemented by pink pills, bile beans, liquozone, and the host of modern remedies whose praise is in all the newspapers. Any old "tante" is the midwife for the neighbourhood and any farmer acts as gravedigger and undertaker when required. Sometimes a medical man has to be fetched from a great distance, but only rich families can afford this, for the fees are a guinea an hour, and ten hours are easily spent on the long roads. Medical knowledge gained by recognised methods of study and observation is, as a rule, not very highly esteemed by the "Boeren," who have a decided preference for the "wonderdokter," and in 1899 there was in the Transvaal a famous specimen of the last-mentioned class of practitioner. During the war he was in Cape Town and the Dutch Afrikanders there believed in him. His fame had, in fact, spread all over South Africa. The Afrikanders are like one big family—what happens in the Transvaal is soon known in Cape Town and *vice versâ*. "Dr. Eugen," as he was called, was quite a celebrity. From far and near the farmers travelled to Pretoria in 1899 to consult him. There was always a file of carts and wagons in his street and inside his door was a crowd peacefully waiting. A consultation always lasted five minutes and the fee was one guinea. As soon as the patient came forward the "dokter" laid both his hands on the former's head and something like an electric current was supposed to pass between healer and subject. The "dokter" knew at once what was wrong. He did not prescribe medicines as he was not possessed of any diploma, but the leading feature of his treatment consisted in regulation of the patient's diet. After his electrical diagnosis he sat in his big armchair and consulted his "spirits" about the different foodstuffs and beverages to be given or withheld. As a rule the farmer had to give up his coffee and wine, which was indeed a very hard trial to the Boer. During winter "Dr. Eugen" left Pretoria for the river Zambesi, where he lived on "drill fish," as they call the torpedo or cramp fish. In this way he got a new store of electricityfor the next season! Sometimes a rich farmer fetched him for an urgent case to his house. This was extremely expensive and the "doctor" would never take the ordinary food placed before the Boer and his family but only a fowl prepared in his own way. Oom Paul Kruger, the late President of the Transvaal Republic, had little faith in this "wonderdokter." He sent for him once but when Eugen began to "consult his spirits" the President asked him to what kind of spirits he was talking. "Are they in heaven?" "I do not think so," was the answer. "Then go," said Oom Paul.

Perhaps there is no part of the world in which patent medicines have such a vogue as in South Africa. Since the greater part of the population come into the world, live, and die without professional aid domestic medicines and some hereditary skill on the part of the farmers have the field much to themselves. No wonder that in this country the newspapers and periodicals, whether daily, weekly, or monthly, contain so many advertisements of patent medicines and preparations for invalids. In a recent issue of the *Cape Times*, our leading newspaper, the following may be counted: (1) Savaresse's Sandal Capsules; (2) Doan's Kidney Pills; (3) Wolfe's Schnapps (*pictures* of 18 tired men!); (4) Carter's Liver Pills; (5) Larola (for the skin); (6) Co-Do (for the mouth); (7) Montserrat; (8) Cockle's Antibilious Pills; (9) Apiol and Steel Pills; (10) Steedman's Soothing Powders (for children cutting their teeth); (11) Zam-Buk (in the news columns); (12) Bile Beans (in the news columns); (13) Sheldon's Digestive Tabules (for indigestion, dyspepsia, &c.); (14) Chamberlain's Cough Remedy; (15) Jones's Rheumaticure (for sciatica); (16) Vichy-célestins (for gout, diabetes, &c.); (17) Kopps (for the hair); (18) Chicago Cold Cure (cures a cold in 24 hours); (19) Cooper Neuralgia Cure; (20) Beecham's Pills; (21) Towle's Pills (invaluable to ladies); (22) Wood's Great Peppermint Cure; and (23) Dr. Shedon's New Discovery. It may here be remarked parenthetically that in the English papers such advertisements in the news columns are always marked *Adv.* Dutch papers may take them without any addition and as a rule with deceptive headlines. Once there was almost a quarrel between the editor and the director of *Ons Land*; the former said: "My readers must see *Adv.* under such articles." "No," said the latter, "our shareholders have our first care." Dr. Sanden's electric belt occupies an advertisement space of about 50 square inches in every issue of our leading papers, Dutch and English, but the pink pills have been much less conspicuous of late. Perhaps this is caused by the harshness of our legislators. Before the new Custom tariff came into force on May 25th the agent for the pink pills paid only a trifling *ad valorem* duty on 7*d.* per 1000, this being the value as per invoice. But now he has to pay £1 sterling for one pound avoirdupois, which is a very different thing. Of course, the farmers are the best customers for patent medicines, but as some of them read little more than their Bibles and a weekly church paper—*De Kerkbode* or *De Vereeniging*—it is no wonder that even these religious papers get a good share of advertisements from the patent medicine vendors, so that next to a highly poetical and edifying explanation of some passage of Holy Writ there may be found a most prosaic paragraph on diseases and their treatment. Every druggist keeps a fairly complete stock of patent medicines as far as he can get hold of them, but some nostrums are not yet to be found in any drug store, because the agents do not wish to surrender any portion of their profits.

Medical men are not popular with the people, not even with the town people, partly because they are said to charge very high fees and partly because they are supposed to be required only for treating diseases of the teeth and for performing operations in which cutting and sewing are necessary. In cases of internal ailments the general idea is that the cheapest and easiest way is to go to a chemist and ask his advice. In 1901 and 1902 there was perhaps as much venereal disease in Cape Town as in any town on the globe, and most of these cases of syphilis and gonorrhœa were treated without a medical man. One druggist had 500 venereal patients in a month and all dealers in medicinal substances laid in full stocks of mercurials and santal midi to be disposed of to customers coming for advice and treatment.

As a rule the Boers succeed very well in rearing their large number of children. At Standerton there is a family with 29 children. When I lived in a farming district in the Transvaal for a year I found that between 10 and 15 children in every house was the average and very few infants died. In Cape Town, however, more than 50 per cent. of the children die in their first year and even among the white people the death-rate is large. Our town council discussed the question in January last with the result that a duly qualified nurse now goes round to the houses where there are infants, examines the little ones, and gives the parents good advice.

I am, Sirs, yours faithfully,

C. J. VAN RIJN.

Cape Town.

CARDIFF AND SWANSEA HOSPITALS.

To the Editors of THE LANCET.

SIRS,—The grounds for your unfavourable criticism in THE LANCET of July 28th of the management of the Swansea Hospital as compared with that of Cardiff for the year 1905 appear to be the relative cost per bed *as* furnished by your correspondent. These were—Swansea, £71 19*s.*; Cardiff,

---

[1] Many pharmaceutical chemists announce in gold letters on their windows that they sell Dutch medicines.

£64 5*s.* 4*d.* Your correspondent in arriving at these results has in the case of Swansea taken the *total* ordinary expenditure, £8214, and divided it by the average number of beds occupied (114·12), with the result (£71 19*s.*) as the cost per bed, but in the case of Cardiff has taken from the total ordinary expenditure, £12,745, a sum of £2606, leaving a balance of £10,139, which he has divided by the average number of beds occupied (157·77) with the result (£64 5*s.*) as the cost per bed. These results are two totally different costs per bed, there being no connexion whatever between them, and any comparison must be absurd. When the expenditure of both hospitals is compared according to the standard laid down by Sir Henry Burdett and adopted almost universally by the London and provincial hospitals, and taking into account the out-patients, painting, and bank charges in both cases, the result would be as follows:—

Year.	Swansea.		Cardiff.	
	Cost per bed after deducting 1*s.* 6*d.* for out-patients.	Cost per bed on total ordinary expenditure.	Cost per bed after deducting 1*s.* 6*d.* for out-patients.	Cost per bed on total ordinary expenditure.
	£ *s.* *d.*	£ *s.* *d.*	£ *s.* *d.*	£ *s.* *d.*
1903	57 0 0	60 5 0	70 15 0	79 15 0
1904	60 0 0	63 12 0	72 0 0	80 15 0
1905	63 0 0	71 19 0	74 0 0	84 10 0

This is not time to criticise the standard adopted by Sir Henry Burdett or to question the right of the Cardiff authorities to adopt any standard they may think fit but if the expenditures of two hospitals are to be compared it can only be done satisfactorily by adopting a common standard for both.—I am, Sirs, yours faithfully,

W. LLEWN. MORGAN, Lt.-Colonel.
Swansea, August 7th, 1906. Chairman, House Committee.

JUVENILE SMOKING.

To the Editors of THE LANCET.

SIRS,—Your annotation in THE LANCET of July 28th, p. 241, on Juvenile Smoking leaves absolutely untouched the point made months ago by the Lord Advocate of Scotland—viz., that cigarettes can be fetched by the bigger boys and secretly sold or given by them to their younger brothers or companions, in which way the proposed legislation would be rendered a dead letter. To suggest that this difficulty is insuperable seems absurd. Yet amid all the writers on the subject not one has told us how to meet the point, nor, strange to say, does the Select Committee make any suggestion. I am, Sirs, yours faithfully,

July 30th, 1906. OBSERVER.

TWO POINTS OF MEDICAL ETHICS.

To the Editors of THE LANCET.

SIRS,—With reference to the letter of "I.M.S." in THE LANCET of July 28th, p. 258, I submit the following opinions.

1. As to "shameful" diseases your first duty is to your employer. The medical officer is employed by the Crown—the person who pays the piper calls the tune—and the sick person has joined the service in full understanding of this fact and, of course, the disease must be stated accurately on the returns. No one can expect you to make and sign an incorrect official statement. Take the case of a man unfit for duty from alcoholism. When you are sure of your diagnosis it must be at once officially reported. If not, you probably show a bad example to, and thereby degrade, your subordinates; you prejudice the service; you very rarely gain anything for your patient, except a putting off of the evil day which will come, and the trouble which follows generally recoils on yourself and serves you right.

2. Officers under treatment by private practitioners. It is most unlikely that a civil practitioner would see without inquiry an officer who was, *a priori*, probably the patient of another. In the unlikely case (I am not talking of consultations which I always encouraged, they comfort the patient and often help you) you may deal with the civil practitioner directly and, of course, if the interruption of your treatment has prejudiced the case, clearly it is your duty to report that to the patient's commanding officer; unless, of course, your withers are wrung and conscience tells you you can do better next time. In this case pocket your experience and put it to profit.

I am, Sirs, yours faithfully,
July 31st, 1906. R. N.

THE INSPECTION OF PORK IN IRELAND.

(FROM A CORRESPONDENT.)

A QUESTION of great importance came before the Belfast corporation on August 3rd—that is, how to deal with the carcasses of swine affected with tuberculosis. The market committee carried a motion[1] to the effect that when the lesion was strictly confined to the glands of the neck the head and neck should be destroyed and the rest of the carcass returned to the owner, but that where two or more organs were affected the whole of the carcass should be destroyed. The committee followed in its regulation the practice in Glasgow, Dublin, and Edinburgh, and in Germany, but when the matter came up for confirmation before the city council it was decided to send back the resolution to the markets committee for further consideration on the ground that the 1898 Royal Commission on Tuberculosis had stated that "in view of the greater tendency to generalisation of tuberculosis in the pig we consider that the presence of tubercular deposit in any degree shall involve seizure of the whole carcass and of the organs"

This matter raises several very interesting subjects for discussion. Everyone admits that proper and thorough inspection is necessary, but many believe that the view of the 1898 Royal Commission cannot, with the evidence accumulated since it reported, be maintained. First, on what evidence is it established that there is a "greater tendency to generalisation of tuberculosis in the pig"? In the case of the very pigs seized recently in Belfast the most careful experiments made microscopically and by injecting the flesh of the animals into guinea-pigs (which are so sensitive to tuberculosis) have totally failed to demonstrate or to produce the disease, though in these same pigs the glands removed were tuberculous. Among the most complete and authoritative treatises on meat inspection is that of Dr. Ostertag, professor in the Veterinary High School at Berlin, and in the fourth edition of his great "Handbook of Meat Inspection," translated in 1904 by Dr. Wilcox, veterinary editor, Experimental Station Record, Washington, with an introduction by Dr. Mohler, chief of the Pathological Division, United States Bureau of Animal Industry, the whole question is very fully discussed. It is demonstrated that the experience of the pathological-anatomists shows in the most unambiguous manner that the meat of tuberculous animals plays only an inconspicuous rôle in the etiology of human tuberculosis. With reference to the view generally entertained that in undoubted cases of local tuberculosis the meat is harmless, Dr. Ostertag says: "The assumption of the harmlessness of meat in cases of undoubted local tuberculosis will probably remain for all time as an immutable dogma of meat inspection"; while in reference to the current notion that the generalisation of tuberculosis is always associated with a harmful property of meat Dr. Ostertag says that this can no longer be maintained, for, according to him, "only under certain conditions, and not uniformly, does the generalisation of tuberculosis produce a harmful property in the meat." It is clear that the opinion of the 1898 Royal Commission cannot be regarded as unchallenged, however perfect the counsel conveyed. Secondly, even were such a rigid meat inspection found to be necessary, it is absurd that it should be applied by one local authority and not put in force by another. Why should carcasses be condemned in one place, which would pass in another where there is a less rigid inspection, or none at all? It is common in several of the smaller Irish towns for pigs to be bought and "cured" without any inspection at all, and what is still more ridiculous, the meat of these animals is sent into Dublin and Belfast where it is used without being inspected at all in its "cured" state. Many hold that meat inspection should be taken out of the hands of the local authorities. The Government could then adopt one uniform method of meat inspection based upon scientific veterinary and medical knowledge. No one wishes to consume the tuberculous meat of any animal, even though cooking renders it harmless, but, while taking every proper precaution by inspection to get rid of such a risk, it must be clearly recollected that the meat of a tuberculous animal plays a comparatively small rôle in the causation of human tuberculosis. The so called panacea of meat inspection must not be allowed to draw away attention from other important factors in the causation of consumption.

---

[1] See THE LANCET, August 4th, 1906, p. 327.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

Liverpool Infirmary for Children.

SINCE the appeal for £10,000 for this institution first appeared sums amounting to £1500 have been subscribed and a further sum of £500 has been promised conditionally on the balance being raised. £13,000 are still required to complete the new building, but of this amount £5000 have been voted by the city council provided the balance is raised by the public. Unless the greater portion of £5000 is contributed by the end of September favourable contracts for the unbuilt portions will lapse and the completion of the infirmary will be indefinitely delayed. The committee is earnestly asking for help to complete the work.

Infantile Mortality in Liverpool.

Infantile mortality is continuing to be a cause of great anxiety to the health committee of the city council. Allusion was made in THE LANCET of July 28th, p. 260, to the provision of special beds at the Royal Infirmary for the treatment of infantile diarrhœa, at the suggestion of the health committee. I have now to record that a similar suggestion was received on July 25th by the West Derby guardians from Dr. E. W. Hope (the medical officer of health) requesting their asistance in mitigating the effects of certain infantile complaints which are causing many deaths amongst young children. The guardians in response have allotted a couple of wards at Belmont-road workhouse for their reception.

Death of Dr. Felix B. O'Flaherty.

By the death of Dr. F. B. O'Flaherty, which occurred on August 1st from cardiac disease, a promising and comparatively young practitioner has been removed from our midst. He was one of several brothers, some of whom fought on the British side in the late Transvaal war, and one of whom lost his life. The interment took place on August 3rd at Flaybrick cemetery, Birkenhead, in the presence of a large concourse of sympathising friends. The deceased was only 45 years of age.

Infantile Mortality in Cheshire.

Mr. Francis Vacher (the medical officer of health of the county of Cheshire) in his annual report for 1905 states that the proportion of infants who died was 9 per 1000 births less than in the whole country, and the proportion of infantile deaths in the municipal boroughs was 22 per 1000 more than in the 76 great towns of the kingdom. This is a fair record as regards the whole county but is a decidedly bad record as regards the municipal boroughs. The variation in weather conditions and the incidence of epidemics influence the general death-rate from year to year and as surely increase or decrease the mortality among infants. The infantile mortality-rate being high in a particular year might be due to the incidence of sun and rain, the passing of a wave of epidemics, and such recondite causes; but the infantile mortality-rate being high year after year in some special district, or part of a district, is not to be explained in this ready way, so that no one can be made responsible. A high infantile mortality-rate in any district must be due to local insanitary conditions in that district, which it behoves the local authority to discover and to remedy. The main causes of a high rate of infantile mortality may be summed up as follows: (1) the employment in factories of those about to become mothers and those who have been recently confined and should be nourishing their infants; (2) the infants of factory-employed mothers being badly cared for and ill fed during the absence of their mothers at work; (3) the environment of the infant being insanitary; (4) there being no provision for isolating infectious children or disinfecting infectious bedding, &c.; and (5) the ignorance common among working women as to how an infant should be fed, clothed, and managed.

August 6th.

WALES AND WESTERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENTS.)

Newport Corporation Bill.

ALTHOUGH the Police and Sanitary Committee of the House of Commons did not approve of all the clauses in the Improvement Bill recently promoted by the corporation of Newport, important provisions have been obtained and they will make for more effective public health administration in the borough. The difficulty of fixing the responsibility for negligent drain-laying and similar work upon the proper person has long been felt. As Mr. T. Pridgin Teale said long ago, if a platelayer places rails so that they overlap and in consequence a train is overturned and some person is killed, that platelayer would be put upon his trial for manslaughter: why cannot the same be done in the case of a drainlayer who lays a line of drains so negligently that a fatal case of typhoid fever is the result? It will in the future be possible to punish such negligence in Newport, for Section 4 of the Corporation Act provides that "if a water-closet or drain is so constructed or repaired as to be a nuisance or injurious to health the person who undertook or executed such construction or repair shall, unless he shows that such construction was not due to any wilful neglect or default, be liable to a penalty not exceeding twenty pounds." A difficulty which is not confined to Newport has been experienced in connexion with the repair of drains. Where these are newly laid or are re-constructed there are already sufficient powers of inspection but in the case of ordinary repairs this is not so. The clause intended to deal with this difficulty was allowed by the committee of the House of Lords and required that 12 hours' notice should be given by any person who desired to repair a drain which should be left open for a period not exceeding 24 hours in order that it might be inspected. The chairman of the police and sanitary committee, however, considered this to be unreasonable and the section as it now stands merely requires notice to be given of the intention to repair and gives free access to officers of the corporation for inspection purposes. The sanitary officers have power under the Act to test drains (though not by water under pressure) when they have reason to suspect that such drains are defective. An attempt has been made to meet the difficulties which have arisen owing to the conflicting definitions of a drain in those districts where the Public Health Acts Amendment Act, 1890, is in force. A drain is defined to include any sewer or drain either already constructed or to be constructed with which two or more houses or premises (whether belonging to the same or different owners) are now or may at any future time be connected. The blowing or inflating of meat is prohibited. The sections referring to tuberculosis in connexion with milk supplies are identical with those in the Rhondda and other private Acts. They include provisions prohibiting the sale of milk for human consumption from cows suffering from tuberculosis of the udder; requiring the isolation of diseased cows and notification to the medical officer of health, giving more or less complete powers of inspection both within and without the district, together with the taking of samples of milk and the summary stoppage of particular supplies. Other sanitary provisions have reference to the regulation of the manufacture and sale of ice-creams. The corporation is also empowered to make by-laws for preventing the pollution of water which it is authorised to take, even though the contamination of the water may take place in another sanitary district.

The West Wales Sanatorium.

At a meeting of the building committee of this institution which was held recently at Alltymynydd it was reported that the sanatorium was approaching completion. The committee hopes that the public will make a generous response to the appeal for further funds which was issued not long ago and anticipates that great assistance will be rendered by the working classes.

Physical Training.

The first of the competitions organised by the Glamorganshire county council for the physical improvement of the children of the county took place at Porth on July 14th. Five towns entered for the competition and Porth was awarded the shield.

The Vaccination of School Teachers.

At a meeting of the Gloucestershire education committee held on July 28th the subcommittee recommended that the committee do not consent to the recognition under Article 11 (e) of the Code for 1906 of teachers who have not been vaccinated. Article 11 (e) provides that "no teacher will be recognised who has not produced a medical certificate satisfactory to the board or who has not been vaccinated. Except that, with the consent of the local education authority, an unvaccinated teacher who has declared to the board his conscientious objection to vaccination may be recognised." An amendment was moved to the effect that no advantage would be secured by refusing to appoint unvaccinated teachers, but this was lost by a large majority, and the subcommittee's recommendation was adopted.

The Western Branch of the British Dental Association.

The annual meeting of the Western Branch of the British Dental Association was held at Exeter on July 20th in the new building of the Devon and Exeter Dental Hospital, Exeter. The secretary reported that the branch had 96 members and that the financial position was satisfactory. Mr. T. A. Goard delivered the presidential address, in which he dealt principally with unqualified practice and the evils of advertisement. Mr J C Wing (Ilfracombe) read a paper on the Strengthening of Vulcanite Dentures, and demonstrations were given by Mr. J. J H. Sanders, Mr. W. H. Lyne, Mr. J. H. Gartrell, and Mr F. T. Haycroft. The annual dinner was held in the evening at the Rougemont Hotel.

The Winsley Sanatorium.

At a meeting of the Bristol health committee held on July 17th the financial position of the Winsley Sanatorium was discussed at considerable length. It was stated that the liabilities of the institution amount to £15,000. The capital sum charged to public authorities for beds by the committee of the sanatorium was much below the actual cost, scarcely more than half, and even if the bodies to whom beds have been allotted pay £100 per bed additional, as has been suggested, the sum will not approach the actual outlay. If this course were generally taken, however, it would relieve the pressure that has arisen, and if the charitable public were to subscribe as well a satisfactory state of affairs would be arrived at. The health committee did not come to any definite decision as regards increasing the contribution to the sanatorium. The city of Bristol has 20 beds in the institution and it is hoped that more money will be forthcoming.

The Didworthy Sanatorium, Dartmoor.

The annual meeting of the subscribers to this institution was held on July 31st under the presidency of the Earl of Mount-Edgcumbe. The sanatorium was opened in 1903 with accommodation for 14 patients, but recently the institution has been enlarged to receive 35 patients, although, unfortunately, owing to lack of funds it has not been possible to keep the beds always occupied. The medical report stated that 66 patients had been admitted during the year ended April 31st and the results had been very satisfactory. The financial statement showed an unfavourable balance of £38. Sir Massey Lopes has endowed the institution by investing £500 in Consols for that purpose, and it is hoped that a greater amount of financial help will be given to the sanatorium so that the good work which it is performing may not have to be curtailed.

August 6th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Medical Appointments to the Glasgow Post-office.

FOLLOWING upon the death some time ago of Dr. William Dougan, who had been medical officer to Glasgow Post-office for a considerable number of years, the Postmaster General decided to make a new departure in connexion with the appointment. Owing to the growth of the department, and the consequent increase in the number of officials employed, it was deemed inadvisable to continue the system of appointing only one medical officer to be exclusively in the service of the establishment. The postal area was divided into six districts and it was decided that a medical officer should be attached to each, the gentlemen appointed being at liberty to engage in private practice. In reply to the advertisement of the positions about 300 applications were received. The Postmaster-General has now made the following appointments: Central district, Dr. D. Watson; western district, Dr. R. O. Adamson; southern district, Dr. W. Lawson; eastern district, Dr. J. Patrick; northern district, Dr. J. McKie; and Govan, Dr. R. Y. Anderson.

Anthrax in Glasgow.

During the past fortnight two cases of anthrax have been admitted to Belvidere Hospital. Both patients were employed in hair works and had worked with hair in its natural state. In the case of the first patient South American and English horsehair were used in the factory at which he worked. When inquiry came to be made none of the English hair remained on the premises, and the South American hair gave a negative result on bacteriological examination. The duties of the second patient consisted in receiving and opening on arrival bales of hog's hair from America. Here also the bacteriological inquiry was negative. The situation of the sore in both cases did not suggest infection through a dust laden atmosphere, but by inoculation through a superficial abrasion on the arm. The medical officer of health, however, has pointed out to the health authorities the danger that arises during the process of teasing the hair. In both factories in which the cases occurred the raw hair after unpacking is teased and mixed by machinery, and during the process, despite the fact that fans are attached to the machine, a considerable quantity of dust is produced. Should any consignment of hair contain anthrax this dust-laden atmosphere must constitute a very grave danger to the workmen.

Tinned Sardines as a Diet for Young Children.

Another series of cases of illness after partaking of tinned food was reported last week by the Glasgow district police. The food at fault was a tin of sardines purchased in a shop in the Southern district and partaken of by a family residing in the district. About one and a half hours later the four children who had partaken of the food developed alarming symptoms and were removed to hospital where they were treated for ptomaine poisoning and ultimately recovered. That there may have been something wrong with the food in question cannot be denied, but the worst feature of the incident is the ages of the children who partook of the food. The oldest was aged five years and the others respectively four years, two and a half years, and nine months. It seems appalling that it is possible for such gross ignorance or carelessness to exist, and it throws some light upon the difficulties with which municipal authorities have to contend in grappling with the problem of the large mortality among children who are reared in cities. The parents are aliens residing in the city, but this does not lessen the gravity of the case so far as the municipal authorities are concerned, for it has come to be recognised that if any improvement in infantile mortality-rate is to be effected it is just this class of parents that will have to be got at and educated.

Practical Inspection of Meat.

A subcommittee of the town council of Glasgow is considering a letter from Professor John Glaister, who states that it has been remitted by the Faculty of Physicians and Surgeons of Glasgow to the President of the Council and himself to approach the corporation requesting its coöperation in the establishment of a course of teaching on meat inspection and of the diseases of animals communicable to man. It has been suggested that this class should be conducted by the chief veterinary surgeon of the corporation.

Hygiene and Salubrity.

The town council of Glasgow has received a letter from the committee of the Association for the Promotion of Hygiene and Salubrity in Dwellings, intimating that the second International Congress of the Association will be held in Geneva from Sept. 4th to 10th. The committee requests that the municipality will be represented at the congress by an official delegation, which would bring forward the fruit of its experience and take part in the discussion of the reports presented.

August 7th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Increase of Lunacy in Ireland.

AN official statement signed by the two Lunacy Inspectors, Sir George Plunkett O'Farrell and Dr. E. M. Courtenay, just made public, says that insanity is undoubtedly growing in Ireland, and the inspectors express the opinion that a cause of this increase is to be found in the emigration from the country of the strong and healthy members of the community, with the consequence that the weak and the infirm, who are more likely to fall victims to insanity, are left behind. The increase, they also say, is partly due to the return of emigrants suffering from mental breakdown, who either come back voluntarily or are repatriated by the United States Government. It is a common fallacy that the amount of insanity is greatest in cities, where the race for life is keen. On the contrary, the inspectors state, statistics prove that the amount of insanity in proportion to population is greatest in remote rural districts, while in the busiest towns the ratio is lowest. The explanation, it is stated, is that the exodus of the strong and vigorous is greater from rural than it is from urban districts. One curious fact is noted in the report, that while in England and Scotland the proportion of females in asylums exceeds that of males, the opposite is the case in Ireland. Tracing the causes of insanity in Ireland, the inspectors find that through heredity there has been a small increase; through alcoholic excess the proportion has fluctuated during the last decade, but in 1901 it was only 8 per cent. higher than it was in 1894. The result of the abuse of drugs has varied considerably. Giving the causes of insanity in the order of their importance, it is found that heredity heads the list, showing, as it does, 36 per cent. of the whole number of cases. Alcohol comes next, being responsible for 25 per cent. of the aggregate total of the cases of insanity.

Poor-law Medical Officers.

Much disappointment has been caused among the Poor-law medical officers of Ireland by the refusal of the Prime Minister to appoint an Irish medical man to succeed the O'Conor Don as a member of the Royal Commission in connexion with the Poor-laws.

The Office of Medical Superintendent Officer of Health of Belfast.

At a meeting of the Belfast city council held on August 1st a letter was read from the Local Government Board, saying "they will be glad if the council will take an early opportunity of reconsidering the recommendation of their public health committee, so that effect may be given to the Board's views concerning the desirability of offering a higher salary than £600 a year for the very responsible position of medical superintendent officer of health of a city of the size and population of Belfast." The Lord Mayor suggested (and this plan was adopted) that the public health committee should consider this letter and said that, if necessary, he would call the council in committee.

Medicines in Monaghan Dispensary.

A fortnight ago Mr. R. A. Crawford, medical officer of Castleshane dispensary district, appeared before the Monaghan board of guardians with a stock bottle which he had taken out of Listraor dispensary depôt and which should have contained liquor morphinæ hydrochloridi but which presented a strange appearance. The guardians having ordered the contents of the bottle to be analysed, this was done with the following scandalous results as testified to by the analyst, Mr. Charles McMullen, of the Chemical Laboratory, Corn Market, Belfast: "The result of my analysis proves beyond a doubt that the bulk of the sample consisted of decomposed urine and also contained a very small quantity of liquor morphinæ hydrochloridi." As a result of this communication it was decided to put the whole facts before the Local Government Board and to ask its advice as to the steps to be taken in what seems to be a most disagreeable matter.

Belfast and District Lunatic Asylum.

At a meeting of the committee of the Belfast Asylum held on August 6th Mr. G. T. Hine presented a report and plan on the proposed villa colony system. He is in favour of the new asylum being constructed (as the medical superintendent, Dr. W. Graham, has always advised) on the villa colony system. He lays emphasis on two ends to be aimed at in laying out an asylum on this system. The one is to segregate the buildings for the two sexes and at the same time to adapt the arrangement of the buildings to the classification and treatment of the different phases of lunacy; the other is to establish as closely as possible the element of home in every building, thus providing the patients with that variety of activities and occupation that have engaged them ere they entered the asylum. In a word, the villa colony system, as elaborated by Mr. Hine, is a village with every house complete in it as a home, yet so managed as to lend itself to economical administration and control as one establishment. The accommodation required at Purdysburn is for 1400 patients, and in the face of the truly terrible Irish statistics on lunacy the building of such an institution must be proceeded with as soon as possible. The committee has fixed upon the system; indeed, guided by its medical superintendent, Dr. Graham, it had anticipated the great advantages in the villa colony system which Mr. Hine dwelt upon. All that is required now is the approval of the corporation for the present scheme.

Down District Asylum.

The report of this asylum for the year 1905 shows that there was nothing of exceptional interest in the character of the cases admitted (163—83 males and 80 females), the type being in the main melancholia with much associated organic and functional disease. The deaths numbered 58, the chief causes being heart disease (21) and pulmonary tuberculosis (14). The average cost of maintenance of each patient was, calculated on the gross expenditure, less repayment of loans, £23 11*s.*, while the net average cost was £22 2*s.* 4*d.* (that is, after deducting repayment of loans, receipts from paying patients, and other miscellaneous receipts). So far as the administrative history of the asylum is concerned, the year may be regarded as one of quiet progress. The increased recovery rate, the reduced death-rate, the freedom from escapes, accidents, and violence, the very rare occasions on which seclusion or restraint was adopted, the improvement in general health, and last, but not least, the still further reduction in average cost of maintenance, all denote a development in the right direction and indicate that the demands made on the institution are adequately met. As a county institution in a comparatively poor country it fulfils the function of dealing as efficiently and economically as possible with the acutely insane and the chronic class of lunatics.

The Lord Lieutenant in Belfast.

His Excellency, the Lord Lieutenant, Lord Aberdeen, has recently paid a State visit to Belfast. On August 1st Lord and Lady Aberdeen visited the Royal Victoria Hospital and the Mater Infirmorum Hospital. On August 2nd his Excellency opened the new hospital for infectious diseases at Purdysburn. He was received by the Lord Mayor, Alderman Dr. J. King Kerr (chairman of the public health committee), and other members of the corporation.

August 7th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Indo-Chinese Medical Service.

AT a meeting of the Academy of Medicine held on July 24th M. Kermorgant read a report on the working of the Indo-Chinese Medical Service. Great progress has been made by the authorities who have already established a number of medical stations, isolation hospitals, maternity hospitals, and the like. They have also told off, for every consular post, certain medical officers to render medical aid to the natives and to notify and to deal with epidemics. The good results of this useful department are already evident by a marked fall in the death-rate and in the frequency of epidemics.

The Hygiene of Diet.

The Société Scientifique d'Hygiène Alimentaire has recently allotted the prizes founded by Dr. de Rothschild, secretary of the society. The first prize was won by an essay bearing the motto "The Dietary (*Ration Alimentaire*) of the Child from Birth to the age of two years." Many striking essays were sent in on the question of milk distribution in large towns. Four prizes in all were allotted. This competitition and the essays submitted therein are the advance guard of the International Congress on the Hygiene of Diet which is to be held at Paris from Oct. 22nd to 27th.

Poisoning by Tincture of Arnica.

At a meeting of the Hospitals Medical Society held on July 26th M. Siredey related the case of a woman, aged 55 years, a chronic alcoholic. She drank by mistake a liqueur glass of tincture of arnica and afterwards suffered from stomatitis with an ulcerated sore-throat. The ulcers were thickly covered with false membrane. The ulceration had nothing to do with the alcohol, which was only of 60 degrees, but was due to the arnica, which is well known to possess irritating properties. M. Balzer related an instance of the application of tincture of arnica followed by cutaneous erythema and generalised eczema.

Arsenic in the Treatment of Whooping-cough.

M. Nittis made some remarks upon the above subject at a meeting of the Hospitals Medical Society held on July 27th. He was led to try the drug through its successful employment in chorea and in asthma and he found that he obtained better results from its use in whooping-cough than from any other drug hitherto recommended. The preparation used was Fowler's solution and the dose was one minim per diem for every year of the child's life. The treatment should be kept up for two weeks but if swelling of the face occurred the drug should be left off for a day or two. If after some weeks the cough returned the treatment should be recommenced. M. Nittis had noticed that under this treatment the cough took on a very benign form, without paroxysms; in fact the disease might be said to be aborted.

Sequestra of the Temporal Bone removed through the Auditory Canal.

At a meeting of the Medico-Chirurgical Society held on July 9th M. Cauzard commenced his observations on the above case by saying that sequestra of the ear belong to one of the three portions which make up the bony skeleton of the ear—viz., the petrous, the squamous, and the tympanic portions of the temporal bone. In addition they might be formed by the ossicles of the middle ear. In the case which he was going to bring before the society the patient had suffered from recurrent polypi of the ear due to an osteitis of the posterior wall of the auditory canal but without any lesion of the middle ear. Despite an operation which was undertaken to remove the inflamed portion, the patient did not get well till five months later. Recovery only followed on a large sequestrum being taken away which was formed by a portion of the tympanic bone. The case was remarkable for the slight interference with the sense of hearing and for the tympanum remaining unaffected. M. Cauzard thought that the original trouble started from a furuncle in the external auditory canal.

August 7th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Appendicitis.

IN the Berlin Medical Society there have lately been prolonged discussions on the subject of appendicitis, the frequency of which is causing a certain amount of anxiety among the general public. An unusual event at one of the meetings of the society was the presence of Count Posadowsky, the Secretary of State for the Interior, who attended because a collective investigation of the whole question is about to be made on behalf of the Imperial authorities. Owing to the great number of speakers the discussion extended over three meetings, so that this year the society continued its sessions until August 1st, although the recess usually begins in the middle of July. Notwithstanding the heat of the weather the three meetings were well attended. In his introductory remarks the President, Professor von Bergmann, said that the present discussion would be devoted only to questions of diagnosis and treatment, pathology, etiology, and operative procedures would not be gone into. Dr. Kraus, professor of clinical medicine, in describing the symptoms of the disease, said that the clinical phenomena were often not in accordance with the anatomical lesions, so that errors of diagnosis were rather frequent. Slight attacks might be treated by medicines given internally, but every case in which the symptoms continued for more than 24 hours must be operated on without further delay. Professor Heubner said that with children operation should be the rule, as in them the disease was more serious than in adults and a fatal issue was more frequent. Professor Orth, the successor of Professor Virchow, said that in about 10 per cent. of the cases operated on the appendix was found to be normal on microscopical examination. On the other hand, appendicitis was found in post-mortem examinations of persons who had died from other diseases or from accidents and in whom no symptoms of appendicitis had been recognised during life. Hæmorrhages into the mucosa of the appendix were not always a symptom of appendicitis but might be the result of injury inflicted during the operation. Professor Israel discussed the question of operating in the interval between acute attacks and said that an operation was not necessary after a purulent appendicitis, in which obliteration of the appendix usually occurred, and when two years have elapsed since the last attack. An operation was indicated (1) when there were chronic pains issuing from the appendix; (2) when several attacks have happened within one year; (3) in pregnant women; and (4) in children. An operation was also to be recommended when a woman expected to become pregnant or when the patient was very nervous about a relapse, or when there was a prospect of the patient residing in a place where surgical aid was not available. It was safer to operate in a quiescent interval than to wait for another attack, because about 50 per cent. of the patients were liable to relapse and because the mortality in operations during the interval was much smaller than in operations during an attack. Professor Rotber said that diagnosis was not so difficult as was supposed. Pain in the right hypogastric region, nausea, and fever were prominent symptoms. His practice was to operate at once, even in the prodromal stage. Dr. Nöggerath described some experiments in which he was able to produce hæmorrhages in the appendix by ligature of the mesenteric vessels; hæmorrhage was therefore not a symptom of appendicitis. Dr. Guttstadt of the Royal Statistical Office reported that the number of cases of appendicitis registered in the Prussian hospitals was 8412 in 1903 and 10,793 in 1904, and that the proportions operated on in these years were 40·4 per cent. and 44·23 per cent. respectively. The majority of patients were of ages between 15 and 25 years. A commission was then appointed to carry out a collective investigation in accordance with the instructions given by the Imperial authorities.

Myiasis Intestinalis.

At a recent meeting of the Verein für Innere Medicin Dr. Wirsung read a paper on Myiasis Intestinalis. He said that grubs of flies were constant parasites in the skin, the intestines, and the naso-pharyngeal cavity of animals. He had seen three cases of this kind in the human species. One of the patients was a child one year of age, in whom a dozen full-grown grubs of the common fly were discharged from the bowels without any pain. Another was a child, five years of age, who passed 13 living grubs of the common fly after the occurrence of some symptoms of colitis. The third patient was a rachitic boy, four years of age, suffering from chronic enteritis, in whom symptoms of fœtid lientery had developed. On the administration of calomel and naphthalin about 50 grubs were passed. The effects produced by this condition were, as a rule, not striking enough to allow an exact diagnosis to be made.

Professional Secrecy.

An interesting decision of fundamental importance was lately given by the High Court of Justice at Leipsic. A woman had contracted syphilis from a man and after his death recovered damages from his brother and heirs. The medical attendant of the deceased was summoned as a witness, but declined to give evidence on the ground that the law imposes silence on medical men as to facts concerning their patients. The plaintiff's counsel, on the other hand, asserted that professional secrecy was no longer binding after the death of the patient. The High Court decided that only the patient himself was competent to release his medical attendant from the obligation of professional secrecy, and since he had not done so it must be presumed that he did not wish the facts concerning his illness to be made public after his death.

Medical men in Germany may therefore henceforth decline to give evidence affecting deceased patients.

A Visit of French Medical Men.

A party of French medical men belonging to the Œuvre de l'Enseignement Médical Complémentaire, a society for post-graduate study, is about to come to Germany for the purpose of visiting the medical institutions of the country. The tour will include several of the larger cities, such as Cologne, Frankfort, Leipsic, and Munich, as well as some of the university towns, such as Bonn, Heidelberg, and Marburg. Three days will be spent in Berlin. A committee has been formed here under the presidency of Professor von Bergmann to entertain the French visitors and to show them the various sights.

August 6th.

ITALY.

(From our own Correspondent.)

The Psychology of Mountaineering.

To day, the Feast of Our Lady of Snow, appears appropriate to the discussion of the "Alpine question" which in many journals, professional and lay, has been provoking animated controversy under a variety of headlines, from "*Il Diritto di Rompersi il Collo*" (the right to break one's neck) to "*La Psicologia dell' Alpinismo*" (the psychology of mountaineering). And certainly there is one aspect of the question which is of present interest—the jeopardy seemingly inseparable from "peak-storming" and the loss of life already so considerable in the season now passing. From Domodossola, on the Italian side of the Simplon, a correspondent writes to me under date August 3rd:—"The week just ended has been simply tragic in mountaineering annals Within eight days the deaths among the 'Alpinisti' have been nine. The last two months, moreover, have registered no fewer than 20 fatal casualties—the latest being that of Christian Zimmermann, who fell headlong from the Burgenflüh, and that of J. Burckart who while gathering edelweiss dropped down a precipice—both men picked up quite dead and horribly mangled." Still, in spite of these warnings the Alpine mania, as some call it, betrays no tendency to diminish; nay, it appears so steadily on the increase as to have prompted scientific inquiry into its etiology, its "prophylaxis," and its cure. Without reverting to Conrad Gessner's "De Admiratione Montium" which, published in the sixteenth century, marks the first enthusiasm for Alpine exploration—an enthusiasm originating, characteristically enough, not in the Latin but in the Teutonic civilisation—there is no doubt that within the last 70 years the passion for ascending to altitudes above the snow-line has from decade to decade gained in intensity till, from being the distinction of a few, it has become the obsession of thousands, organised into clubs and animated by a spirit of competition quite international. Beginning on the northern aspect of "the water-shed" it has infected the southern or Latin side so powerfully as to make the Italian a formid able rival to the German not only in deeds of daring and in the observation and research, which in the eyes of many are its redeeming concomitants, but even in the vindication of it as a means of physical and moral discipline—a palæstra, in short, out of which its votary emerges a more virile and effective citizen. "Alpinisti," like the late Quintino Sella and the happily surviving Angelo Mosso, have no equals in this latter pleading—Mosso's work, in particular, marking an epoch in the utilisation of mountaineering in the scientific, hygienic, and educative sense. To the compatriots of these pioneers belongs the classification of Alpine clubmen into three distinct groups: (1) the nature student. (2) the artist, and (3) the sportsman. Under this last head a recent Italian "Alpinista" dwells enthusiastically on the benefit already wrought on his compatriots by the intelligent, circumspect, and systematised practice of mountaineering, and predicts for it a future which will see the Latin race emerging from its "shallowness, effeminacy, and weakness, moral as well as physical," into a truly "Anglo Saxon virility of mind and body." So pursued, mountaineering becomes a real "palæstra vitæ" and merits all the encouragement it is receiving from the Italian medical schools, particularly those of Genoa, Turin, Pavia, and Padua. Its disadvantages, not to say dangers, will disappear in proportion as the scientific element impregnates and controls its practice, and this element Professor Mosso has inculcated and driven home in treatises already classic which in foreign renderings enjoy a popularity far beyond their original public. In the first place, like all discipline, it must find its votary in a condition, mental as well as physical, adequate to the demands it makes on him. He must not enter upon it till his mind has been cleared, his physique braced, and his endurance or "staying power" ascertained. How many cases, Mosso has asked, in which the victim has been found dead at the bottom of a crevasse, are to be explained not by unsteady footing or non-recognition of danger but by cardiac lesion declaring itself at the critical moment when all the energies of mind and body should have been at their best? The tragic death, some ten years ago, of Baron Peccoz on the Lyskamm in the presence of the Queen of Italy, set down at first to a misplaced step, was afterwards shown to be due to arterio-sclerosis—to a cardiac condition that contra-indicated the exercise of which he and his Royal companions were so passionately fond. With such precautions as medical diagnosis can suggest and with such practical guidance as experience has put on record, the danger, seemingly inseparable from mountaineering, ought to be minimised and its benefits reaped with a smaller percentage of casualties than the traveller is exposed to on the railway or the motor-car. Such is the net result of the vivacious and interesting discussion on "Alpinismo" which has been enlivening the Italian press these last few weeks, and if its lessons are intelligently put in practice we can sympathise with the forecast of Sella and Mosso when they saw in mountaineering a "palæstra vitæ" conducive to a development which in the case of Italian youth particularly is equivalent to a moral and physical rehabilitation.

August 5th.

Middlesex Hospital Medical School.—The following is a list of the scholarships, prizes, and medals awarded for the session 1905–06: Class Prizes.—Practical pharmacy, S. J. Lee; chemistry, E. W. Hall and S. L. Tressider (equal); biology, R. C. J. Doughty and E. W. Hall; organic chemistry, G. O Teichmann; histology, R. W. Annison and A. C. English (equal); physiology, R. W. Annison; practical anatomy, J. B Tackaberry; anatomy, H. G. Kilner and J A. Rose (equal); pathology, R. M. Peake; bacteriology, E. L. Kennaway and C. F. Robertson; forensic medicine and public health, E. L. Kennaway; psychological medicine, C. H. S. Webb; practical midwifery, R. M. Peake; practical surgery, C. F. Robertson; practical medicine, J. T. Daly; midwifery, C. H. S. Webb; and medicine, E. L. Kennaway. Scholarships, &c.: Second year's exhibition, H. G. Kilner; Leopold Hudson prize, M. L. Hine; Lyell medal and scholarship, A. O Morson; the governors' prize, M. L. Hine; Hetley clinical prize, M. L. Hine; Freeman scholarship, F. E. W. Meadows; and Broderip scholarships, M. L. Hine and F. E. W. Meadows, equal.

The United Operative Plumbers' Association.—At a meeting of the United Operative Plumbers' Association of Great Britain and Ireland held at King's College on July 31st there was a large attendance, including representatives of the building trade and various public bodies. Sir Albert K. Rollit, who presided, supported by the general secretaries of the Trades Unions of Stonemasons, Plasterers, Carpenters and Joiners, and others, expressed on behalf of the governors and council of King's College their warm appreciation of the services rendered to the educational work of the College by the Plumbers' Company and the Carpenters' Company. He referred to the great impulse given to the cause of technical education generally by the guilds of London. The master of the Plumbers' Company (Mr. W. D. Caröe) referred in the course of an excellent speech particularly to the practical coöperation set up between the plumbers and the public health and water authorities in regard to the regulations affecting the health of the community and the greater economy in the distribution and use of water for domestic and other purposes. He alluded to the perfection of the work of the middle ages and later period and dwelt upon the hereditary character of the training of craftsmen and the reverence for accumulated experience. Mr. Randall, on behalf of the association, expressed their appreciation of the aid rendered by the Plumbers' Company to maintain the principle of apprenticeship as the basis of training for the craftsmen and called attention to the influence often exercised by the spirit of commercialism overruling the spirit of craftsmenship by looking to the output of work rather than the quality and finish of the product.

MEDICINE IN TORONTO.

III.[1]

THE POSITION OF MEDICINE IN ONTARIO IN 1850, WITH AN ACCOUNT OF SOME OF THE MEDICAL INSTITUTIONS AT THE PRESENT TIME.

OUR last article dealt mainly with the history of the Medical Faculty of the University of Toronto previous to 1850, and discussed the steps taken in regard to its foundation. Before going further into the history of the development of the medical school in connexion with the University we may well consider more fully than we have done the establishment of Trinity College Medical School and some other of the medical institutions of Toronto, as well as the part played by the Medical Board of Upper Canada, which counts for much in the history of the medical profession which it served.

As stated in the first article, the board was organised by Act of Parliament in the year 1815, and, in the words of the Act, was endowed with the authority to examine all persons desirous to apply for a licence to practise physic, surgery, and midwifery, or either of them, within the province of Upper Canada, and being satisfied with such examination that any person is duly qualified to practise physic, surgery, or midwifery, to certify the same under the hands and seals of two or more of such board, in order that a person so applying may obtain a licence. The board consisted of five or more persons, and from the year 1815 up to 1865, with the exception of a lapse of less than two years when the College of Physicians and Surgeons had its short existence from 1839 to 1841, performed its functions ably. Dr. Christopher Widmer was for many years president of this board. The course the board pursued in the examination of candidates in 1847 was as follows. First, some acquaintance with Latin was required of a candidate. With this view, if a candidate could not construe some paragraphs of Gregory's Conspectus, a portion of the *Pharmacopœia Londinensis* or a Latin prescription was substituted; in the event of a total failure in these the professional examination was not proceeded with. If the Latin examination was satisfactory then followed, secondly, materia medica and pharmaceutical chemistry; thirdly, anatomy and physiology; fourthly, the theory and practice of medicine; fifthly, practical surgery; and sixthly, midwifery and the diseases of children. It will be gathered from the above that the examination was for that period fairly comprehensive, and the board seems to have fulfilled its duties conscientiously and with due regard to the interests of the public and to the dignity of the profession. The board continued its meetings up to the year 1865 when it was finally dissolved, its functions having been much superseded.

FIG. 9.

Dr. James Bovell.

The establishment of Trinity College Medical School has been referred to cursorily. It was mentioned that its establishment was owing to the fact that the State University of King's College had been wrested from the control of the Church of England. The then Bishop of Toronto, Dr Strachan, took up the matter in the interests of the Church of England population of Ontario, and in April, 1850, went to Great Britain with the object of securing a charter for a Church of England university to take the place of King's College. Sectarian feeling ran high in Ontario in those days, as is shown by a statement made by the bishop on the eve of his departure for England. He said: "The College or University of Toronto is founded on the ruins of King's College, whose royal charter it has repealed, under the pretence of amending it, and whose endowment of eleven thousand per annum, though secured by a patent from the Crown and guaranteed by the pledge of three kings, it has seized and appropriated to itself." In the course of the summer of 1850 Dr. Hodder and Dr. Bovell projected and organised a school of medicine which was advertised as the Upper Canada School of Medicine. When the Bishop of Toronto who had succeeded in obtaining a charter, returned from England, a deputation from this school waited upon him and tendered their services as the medical faculty of the projected university. This offer was accepted, the Upper Canada School of Medicine became the medical faculty of the new Church of England University, and lectures were commenced at once. The Medical Faculty, indeed, commenced its duties in the autumn of 1850 before a beginning had been made with the erection of a university building.

Professor Macallum, in reference to the old Trinity Medical Faculty, informs us that it became defunct about 1858 and between its decease and the foundation of Trinity School of Medicine (which became Trinity Medical College in 1878) 15 years elapsed. The Faculty of Medicine of Trinity College in 1850 consisted of the following members:—Professors: Obstetrics, Dr. E. M. Hodder; Institutes of Medicine, Dr. James Bovell; Surgery, Dr. Henry Melville; Anatomy and Physiology, Dr. U. Bethune; Practice of Medicine, Dr. F. Badgley; and Materia Medica and Therapeutics, Dr. W. Hallowell. Of these the best known were Dr. Hodder and Dr. Bovell. We published a portrait of Dr. Hodder in the previous chapter, together with a brief note on his life. Dr. James Bovell, his colleague in the foundation of the Trinity Medical Faculty, was a very interesting man. He was born in the Barbados in 1817 and studied medicine in London, Edinburgh, and Dublin. He came to Canada in 1848 from Barbados, where he had been in practice, and settled in Toronto, where he soon acquired a large connexion. He became Professor of the Institutes of Medicine and Dean of the Medical Faculty in Trinity College and in 1851 he assisted in founding the *Upper Canada Medical Journal*, the first medical journal published in the province. A deeply religious man, some 10 or 12 years after he came to Toronto he wrote several devotional works which attained considerable popularity. The Bishop of Antigua urged upon him the duty of taking orders, so great was his influence for good among all classes. He was accordingly ordained and spent the rest of his life as a missionary in the West Indies. Dr. Bovell died in the Barbados on Jan. 16th, 1880.

We can get a fair idea of the progress that medical science in its general aspects had made in the capital of Upper Canada by 1850 if we consult Rowsell's Toronto and County York Directory for the year. We find that in 1850, the Medical Board being the directorate, medical studies could be pursued at the Toronto General Hospital, among the trustees of which were Dr. King, Dr. Widmer, and Dr. O'Brien; the Toronto School of Medicine, of which Dr. Rolph was the guiding spirit; Trinity College Medical

---

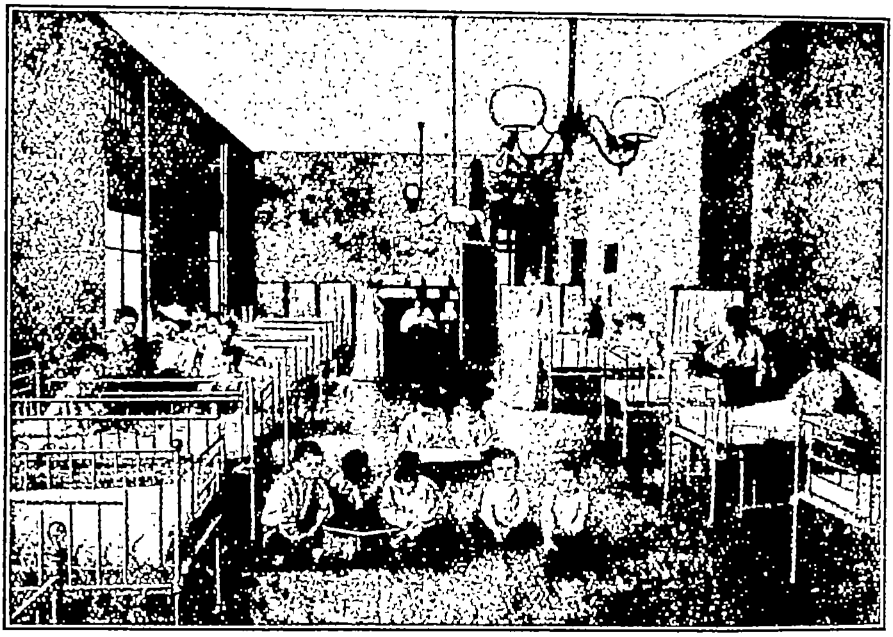
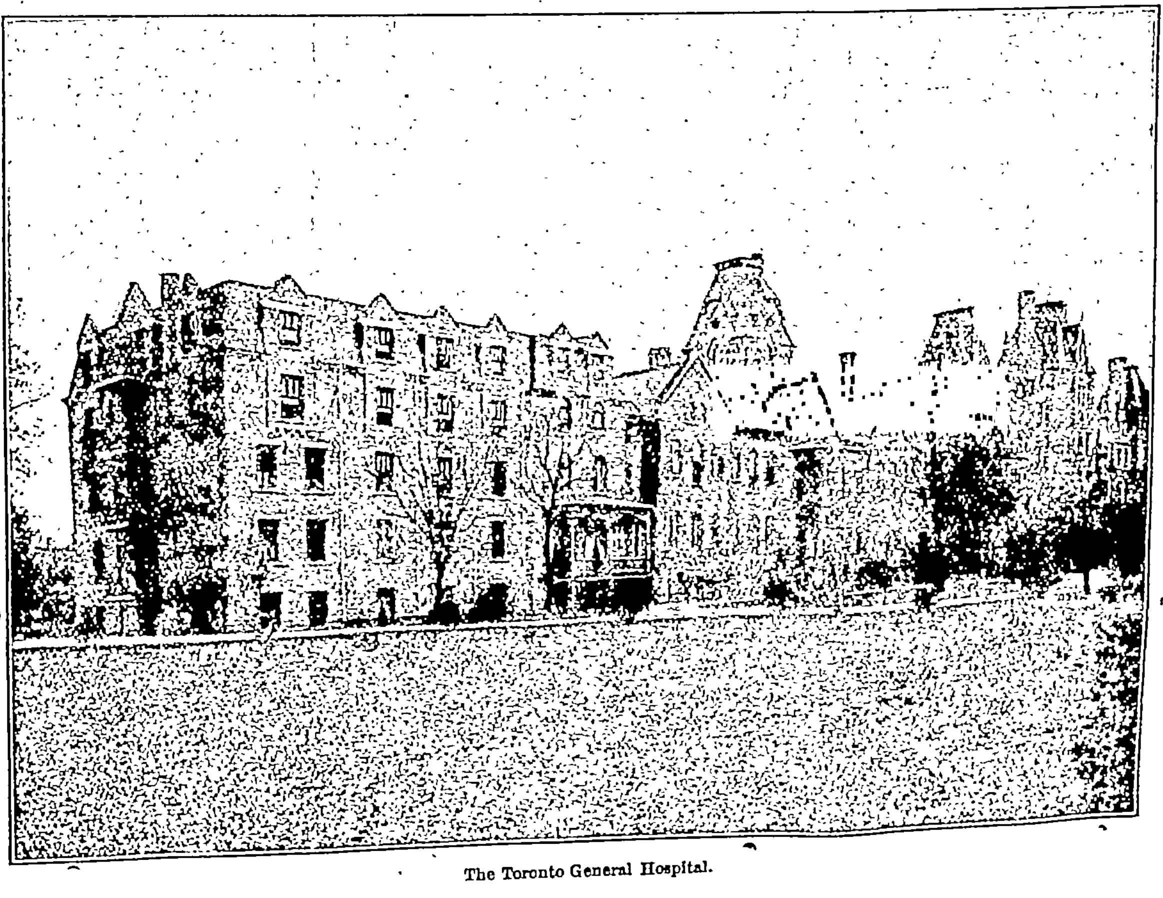
FIG. 10.



Ward in Sick Children's Hospital.

FIG. 11.



The Toronto General Hospital.

School; Toronto Eye Infirmary; Toronto General Dispensary and Lying-in Hospital, established in 1848 (the first of its kind in Toronto); Provincial Lying-in Hospital and Vaccine Institute; Maternity Lying-in Hospital and General Dispensary; and the Catholic Orphan Asylum. There were also a board of health for Upper Canada and a provincial lunatic asylum.

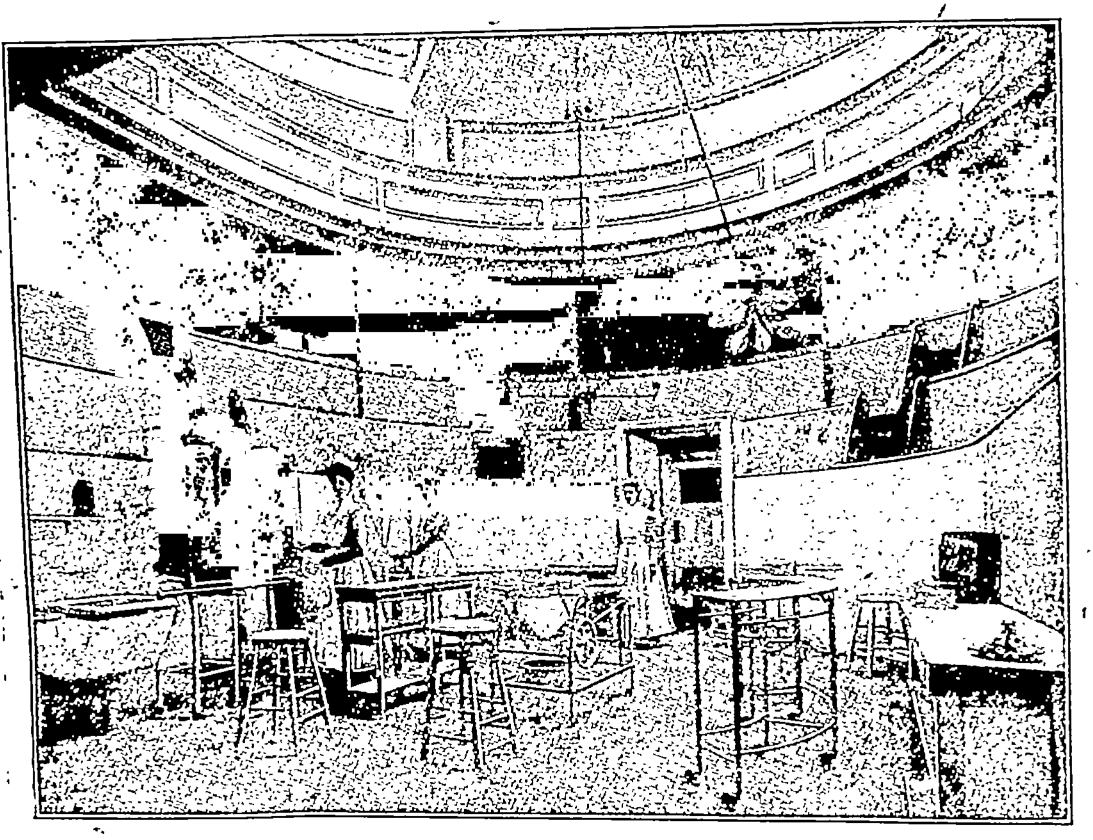
The Toronto General Hospital is described at that time as being 107 feet long by 66 feet wide and two storeys in height, with two other buildings attached thereto for fever patients. The number of patients at that time was said to average 100. Curiously enough, it has not been possible to obtain a picture of the old hospital, but we may be certain it was very different from the imposing building which at present goes under this title (see Fig. 11).

Among the new medical institutions erected since 1850 one of the most deserving of notice is the Hospital for Sick Children. The building used for this purpose is a large one containing 160 beds, and is thus one of the largest hospitals in the world devoted solely to the diseases of children. One block is situated on Toronto Island, in the bay just off the city, and is admirably equipped. The Faculty of Medicine has had for some years the advantage of the splendid opportunities for training in the diseases of children provided by this institution. Resident assistants are appointed annually from the graduates in medicine of the University and hold their position for the year. To Mr. J. Ross Robertson, the author of "Landmarks of Toronto," is chiefly due the existence of this splendid institution. The writer of these articles was taken upon a visit of inspection of this hospital by Mr. Robertson, whose enthusiasm in behalf of the institution was reflected everywhere in the scheme of management and in the domestic details.

There is only one medical college for women in Canada and that is the Ontario Medical College for Women in Toronto, founded in the year 1883. Dr. Michael Barrett, in the University of Toronto at the nsible for its foundation. The formal opening of the Women's Medical College took place on Oct. 1st, 1883. The number of students who have graduated from the college is 112. There are now 32 students in attendance at the college.

Brief mention has been made in a former article of the old General Hospital and we will now describe the present building which took its place. The old Toronto General Hospital was situated in King-street and continued in use until the erection of the present hospital in Gerrard-street, after which the old building was torn down. The second and present hospital occupies a space of four acres, on the north side of Gerrard-street East. The hospital buildings, constructed in a rectangular shape, are 170 feet long with an average width of 120 feet. The main building is built of white brick with stone dressings and is three storeys high, with a central tower 100 feet in height, with smaller towers at each angle of the front elevation. This main building is used for the accommodation of ordinary medical and surgical cases and contains 17 or 18 public wards and several private wards. The operating theatre is in the centre and is flanked on either side by a wing. It is an up-to-date theatre in every way, properly equipped, lighted, and furnished, as may be seen from the subjoined illustration reproduced from a photograph by Dr. Powell. Connected with the main building by bridges are the fever hospital and the Mercer Eye and Ear Infirmary. In the north-west angle of the grounds is the Burnside Lying-in Hospital, which is supported by voluntary contributions, by the fees of students in attendance, and by a yearly Government grant. This building, as well as the eye and ear infirmary and the fever hospital is of the same style and material as the main structure. Between the lying-in hospital and the main buildings is a structure which serves as a resort during the day for convalescent patients and immediately to the east of this are the mortuary, laundry, and other buildings. The wards are roomy and well ventilated, and Toronto has reason to be satisfied with

FIG. 12.



Toronto General Hospital: The operating theatre.

its General Hospital, even while it is obvious that in the near future provision commensurate to the needs of a growing city will have to be provided.

But it has become more and more evident recently that the very rapid growth of the Medical School of the University of Toronto demands greater hospital facilities than have been hitherto available. During the past few years endeavours to grapple successfully with the difficulty have been made from time to time, and much has been accomplished in this direction. Mr Cawthra Mulock's generous gift of £20,000 to the out-patient department has relieved the pressure on that branch of the hospital, and has been followed by a strenuous attempt to raise a sum sufficiently large properly to reorganise the whole institution in such a way that it would amply meet the needs for clinical teaching of the University Medical School. Negotiations with this object in view are at the present time proceeding between the Government and the University, and it is confidently anticipated that the city of Toronto will render substantial aid in order to further this desirable end. From these sources and from private subscriptions there can be but little doubt that the necessary funds will be readily forthcoming. A scheme is afoot, the details of which will be completed shortly, for the provision of a large, modern, and thoroughly equipped hospital which will place the University Medical School in a position to pursue its teaching under the most favourable auspices.

(To be continued.)

Obituary.

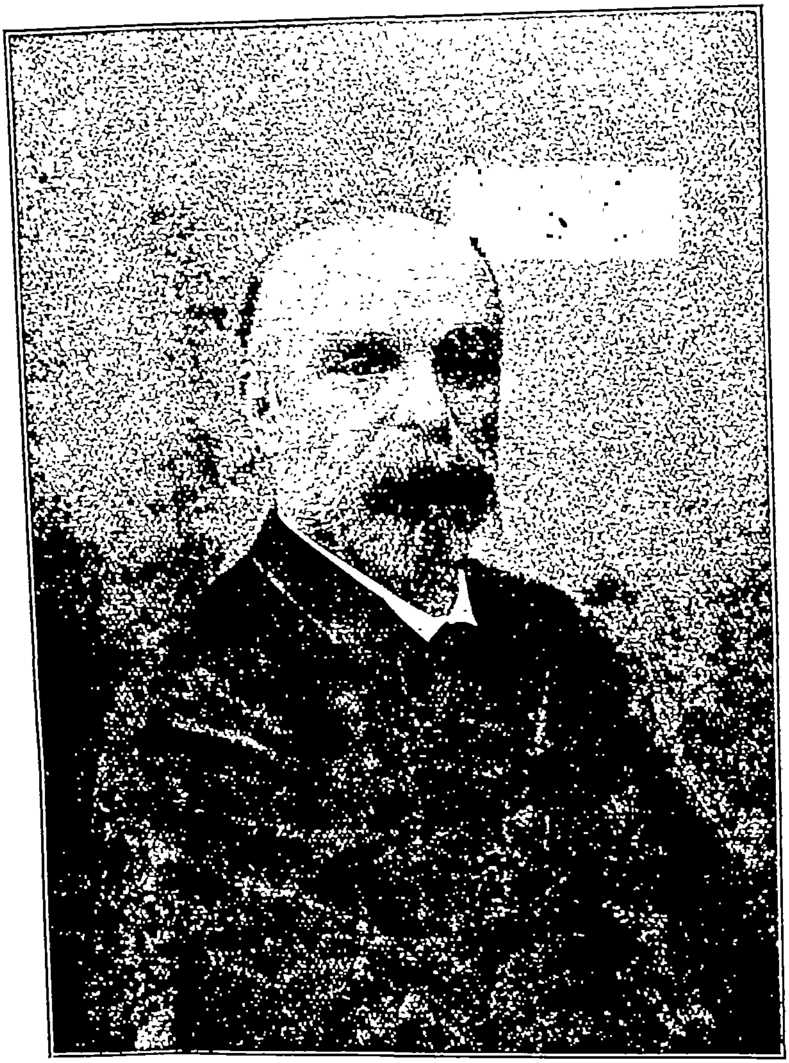
PROFESSOR BROUARDEL.

ONE of the most commanding personalities of French medicine has disappeared owing to the death of Professor Brouardel, whose reputation was spread throughout the world, and whose work and teachings were especially well known in this country which he had visited many times, notably for the British Congress on Tuberculosis held in London in 1901. For 30 years he was among the mouthpieces, and generally he was the chief, of the medical profession of his native country at international congresses, indeed, he represented France officially at almost every congress and meeting held abroad of recent years. His mental activity, which was something extraordinary, found its chief field in questions of legal medicine, hygiene, and medical legislation, on which subjects he wrote many and valuable treatises.

Born at St. Quentin in the department of the Aisne on Jan. 13th, 1837, he studied medicine at the Faculty of Paris, becoming an interne of the hospitals in 1859 and graduating as Doctor of Medicine in 1867. In 1869 he was nominated, at the Concours, physician to the hospitals and a professeur agrégé at the Faculty of Paris. His first wish was to devote himself to pure medicine, for he had been the pupil of Lorain. In this section of medical science he published papers upon Tuberculosis of the Genital Organs of Women (1865); upon Lesions of the Temporal Bone (1866); upon the Conditions of Infection and Propagation of Small-pox (1870); upon the Analysis of the Gases of the Blood (1870); upon the White Corpuscles in the Blood of Small-pox Patients, of the Wounded, and of Women during the Puerperium (1874); upon Vaccination and Small-pox (1869, 1870, and 1874); upon Rabies in Man (1874); upon Glanders and Farcy in Man (1876); and upon Variations in the Quantity of Urea excreted in Maladies of the Liver (1876). In 1877 he published the great work of his master, Lorain, which he had concluded with his own hand, the subject being the Temperature of the Human Body and its Variations in Different Diseases. Soon, however, the study of legal medicine engaged his attention completely. As assistant to Professor Tardieu, who was then the titular head of this department at the Faculty of Paris, he was struck by the insufficiency of the means which then existed for instructing students in this subject, and after the example of Professor Tourdes of Nancy, who made his pupils assist him at post-mortem examinations, he organised at the Paris Morgue classes with practical demonstrations for the students. These classes he continued throughout his life, although the place is damp, very insanitary, and unable to be enlarged because of its site upon a small island in the Seine, while it cannot be transferred anywhere else, for the inhabitants of every quarter of Paris have objected to having a new Morgue in the quarter where they dwell. It is probable that the gradual breakdown in his health took place owing to the insanitary surroundings of the Morgue.

In 1879 Professor Brouardel succeeded Tardieu as professor of the chair of legal medicine and in the same year he was nominated expert in legal medicine to the courts. On him devolved the duty of drawing up all the medical reports for all important trials during the last 30 years, and it will be remembered that he came to Bournemouth in company with Professor Charcot to inquire on behalf of the French Government into the state of health of the well-known Cornelius Herz. The medico-legal reports which he wrote, and of which he published a large number, are models of their class owing to the lucidity of their style, the clearness of their diction, their logic, and the ingenuity of their conclusions. They were published in a special review which he edited under the name of "Annales d'Hygiène Publique et de Médecine Légale." Sundry other publications on the same kind of subject were the following: Studies of Medico-legal Post-mortem Examinations at the Morgue (1878); a Medico-legal Study upon the Combustion of the Human Body (1878); on Rape during Hypnotic Sleep (1879); on Poisoning by Chlorate of Potash (1881); on Causes of Error in Expert Opinions upon Attempts upon Chastity (1884); on Traumatic Diabetes from the Point of View of Medico-legal Expert Evidence (1888); a Medical Study upon the Death of Baron Reinach (1893); and many others of which the enumeration would take up too much space. Besides these he published many volumes upon legal medicine such as the Toxicological Laboratory (1891); the Seal of Medical Confession (Secret Médical) (1893); Death and Sudden Death (1895); Asphyxia by Gases and Vapours (1896); Hanging, Strangulation, and Drowning (1897); Explosions and Explosives from a Medico-Legal Point of View (1897); Infanticide (1897); and Medical Responsibility (1898). All these works, however, which would have reflected credit on any man were only a small part of his labours. In 1886 he was chosen Dean of the Faculty of Medicine of the University of Paris, a post which he filled for 14 years, and during the tenure of which he contributed in a great measure to the reorganisation of medical studies. He was a member of the Council of the University and of the Superior Council of Public Instruction; he was strongly in favour of the creation of an Institute of Colonial Medicine for Paris and of special diplomas for forensic medicine and sanitary medicine. He reorganised the studies in odontology and brought about the creation of examinations for the granting of a diploma of dentistry at the Faculty of Medicine of Paris.

During the latter years of his life, however, the subjects of hygiene and of public health absorbed all his attention. Never an epidemic occurred in France but he was given the duty of investigating it, and his reports upon the following epidemics excited widespread interest: on the Epidemics of Cholera at Marseilles and Toulon (1884); on Sanitation in the Town of Toulon (1885); on the Appearance of an Epidemic of Cholera at Marseilles (1885); on the Epidemic of Miliary Fever (*Suette Miliaire*, Picardy Sweat) in Poitou (1887); and the Origin of Epidemics of Typhoid Fever (1887). Becoming a member of the Consultative Committee of Public Health in 1879 he was president from 1884 to 1903, and upon him devolved the duty of representing France at all the International Conferences of Hygiene at Dresden, Venice, Rome, and Paris. To him as much as to anyone is due the generally recognised view that typhoid fever is mainly a water-borne disease. It was he who drew up the text of the International Regulations for Maritime Sanitation, and it was he also who drafted the Public Health Act of 1902, which is the authority in France for all matters of public health. Brouardel took a great interest in the struggle against tuberculosis and represented France at the congresses on the subject held at Berlin and London, while to him was due the organisation of a scheme for fighting tuberculosis in France by the multiplication of sanatoriums and dispensaries. In this branch of his work he met with great difficulties, for the plan involved enormous expense, and the lengthy periods during which the scheme was in abeyance made it possible to see the results of a similar plan which had been carried through in Germany. From German experience it was evident that the good results



PROFESSOR BROUARDEL.

obtained by sanatoriums were by no means commensurate with the expenses which their construction and upkeep involved and it is possible that France was here no great loser by the checks to Brouardel's energy.

Another portion of Brouardel's life work was devoted to the interests of the medical profession. Thus he was president of the Syndicate of Medical Men of the Seine, of the Union of Medical Syndicates of France, and of the General Association of Medical Men in France, while there were few scientific or professional societies over which he did not at one time or another preside. He was in a way the Pontifex Maximus of French medicine, always considered as the chief by his colleagues and always consulted by the Government as to any question involving medical matters or medical men. No one else in the medical profession played so important a social rôle.

He was a man of prodigious activity and an untiring worker, paying personal attention to the innumerable letters which he was constantly receiving upon all sorts of subjects. Those who came to consult him always retired from the interview satisfied and full of hope, and, a thorough diplomatist, he occupied a very delicate post for many years, although naturally enough he did not succeed in pleasing everyone. Now, at the age of 69 years, he is dead. He died from tuberculous laryngitis which ran a rapid course, and in the treatment of which he displayed but little of the prudence which he would have urged so emphatically upon others. For he had suffered for many years from diabetes and must have known his risks, yet he was continually smoking cigars and refused to abate any of his multifarious activities unless he was absolutely obliged to do so. He was loaded with honours, had been a Member of the Academy of Medicine since 1880, was a Grand Officer of the Legion of Honour, and the recipient of innumerable foreign decorations. He married late in life and had no children, but up to the beginning of this year his aged mother was still alive and happy in the devotion and attention shown her by her son.

EDWARD FRANCIS WILLOUGHBY, M.D. LOND., D.P.H. CANTAB. & LOND., M.R.C.S. ENG.

BY the death of Dr. Edward Francis Willoughby on July 29th, after a brief illness, the medical profession has lost a member who was widely respected for his erudition and esteemed for his personal character. Dr. Willoughby was a native of Warwickshire and a student at University College, London. He became qualified as a Member of the Royal College of Surgeons of England in 1865. In 1869 he graduated as M.B. of London with honours. Soon afterwards he established himself in medical practice in the north of London and continued in the exercise of his profession till his death. In 1881 he added the D.P.H. of Cambridge and of London to his qualifications and became M.D. in 1889. Until almost the day of his death his intellectual activities were many and varied. While keeping himself abreast of the latest advances of medicine he had for many years devoted an increasing measure of attention to questions of public health. He was the author of a "Health Officers' Pocket-book," "Hygiene for Students," and a manual for the farm and laboratory on "Milk." Numerous papers on hygiene or allied subjects flowed from his pen, which was almost never idle during intervals of leisure from professional duty. These appeared from time to time in the "Encyclopædia Medica," von Ziemssen's "System of General Therapeutics," the Transactions of the Epidemiological Society, and our columns. Sometimes he dipped into general literature, as when he edited the Prologue to the "Canterbury Tales." Besides being a member of the British Medical Association he was also on the roll of the Epidemiological Society, the Society of Medical Officers of Health, and the Royal Sanitary Institute, and was honorary medical officer to the Mansion House Council on the Dwellings of the Poor. A good man, an enthusiast in his profession, a scholar, and a gentleman, he will be long remembered by those who have enjoyed the privilege of knowing him.

OSCAR THOMAS WOODS, M.D. T.C.D., L.R.C.S. IREL.

Dr. Oscar T. Woods, medical superintendent of the Cork District Asylum, died on Thursday night, August 2nd, after a protracted illness. The announcement caused sincere regret not alone amongst his medical brethren but also amongst the citizens generally. Dr. Woods was born at Birr, King's County, and was 58 years old at the time of his death. He studied at Trinity College and graduated at the University of Dublin. Soon afterwards he went to England and was appointed medical officer of the Warwickshire Asylum. After holding that position for some time he returned to Ireland and was appointed medical superintendent of the Kerry District Asylum at Killarney. He held that post for 11 years and was then appointed medical superintendent of the Cork District Asylum. During his tenure of office in Cork he effected many improvements in the asylum and was ever most energetic in his efforts to ameliorate the sad lot of the afflicted inmates of the institution. A strict disciplinarian, he was always kind and considerate to all with whom his official duties brought him in contact. Though Dr. Woods's position was a remunerative one it entailed many cares and anxieties. During his 17 years' tenure of office the increase in the number of patients became so great that the accommodation ceased to be at all adequate. Pulmonary tuberculosis became prevalent and Dr. Woods pointed out to his board the dangers likely to occur unless the congestion were relieved. As the result of his representations an auxiliary asylum was recently built at Youghal and some of the comparatively chronic inmates were removed there. A serious outbreak of enteric fever in the Cork Asylum some 12 months ago taxed Dr. Woods's resources to the utmost, and he exhibited much care and discrimination in his endeavours to trace the cause. He always displayed the greatest tact and judgment in the management of the asylum and it was generally recognised that he was a most efficient officer. Alienists recognised his great ability and attainments and in the year 1901 he was elected president of the Medico-Psychological Association of Great Britain and Ireland. During that year the members assembled in congress at Cork and were most hospitably entertained by their president.

WILLIAM JAMES MARTIN, M.D. ST. AND., F.R.C.P. EDIN.

Dr. W. J. Martin, who had been well known in Dublin for the last 50 years, died on August 4th at his residence, 17, Harcourt-street. He was physician to Jervis Street Hospital for a long period, visiting surgeon to the Richmond District Lunatic Asylum, secretary to the Board of Superintendence of the Dublin hospitals, and medical referee to the Sun and other assurance companies. Dr. Martin was very popular and much esteemed by the members of his profession as also by a large circle of friends, to whom the news of his death came as a grievous shock, though he was known to be in delicate health for some time. He was son of the late James Martin of Cappagh, co. Dublin, and brother of the late Sir Richard Martin, Bart.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. Albert Voss, director of the Prehistoric Section of the Royal Berlin Museum. He originally practised medicine but early in life his great interest in anthropology and prehistoric science led him to give up the practice of his profession.—Dr. Adolf Witzel, professor of odontology in Jena, aged 58 years.—Dr. Georg Wilhelm August Meyer, formerly director of the Osnabrück Insane Asylum, described in the Germany medical press as the Nestor of German alienist physicians.

NOTES FROM INDIA.

(FROM OUR SPECIAL CORRESPONDENT.)

Indian Medical Service: Reorganisation Scheme.

THE following alterations of the rules for the allotment of officers by the Indian Medical Service to commands have been published. Prior to 1896 officers were appointed to one or another of the three presidential cadres but since that date officers have been allotted to a military area and have been liable to serve anywhere, though ordinarily employed in the area originally selected by them. This system has resulted in numerous difficulties in arranging transfers, leave, provision of substitutes, and so on. The scheme now is to amalgamate the presidential and general lists and officers will not retain any lien on the areas of their choice except of employment in a civil capacity. Fresh officers will be liable to be sent anywhere for civil employment but will be allowed, according to the requirements of the service, a choice of certain areas. All this means that fresh powers have been given to the heads of the service as against the wishes of the individual officer and that fixity of tenure has been abolished. Fresh officers will be posted to the areas of those military commands in which these officers have expressed a desire to serve. It is difficult to see where the individual officer benefits but it may simplify work at headquarters. The danger is that this new ordinance may lead to undesirable favouritism and patronage.

Some Indian Statistics.

The incorrectness of Indian vital statistics is well illustrated by certain registration returns of two towns in Assam. The birth-rate of this province varied in 1905 from 69·16 at Barpeta to 1·7 at Jhalakati and the death-rate for these two towns was 55·21 and 4·77 respectively. Barpeta is a sacred town to which Hindu women resort. The returns from the other place are unexplained.

Kala-azar in Assam.

The fatal disease of kala-azar seems to be decreasing in Assam, as last year only 3030 deaths were reported, two-thirds of which occurred in the Sylhet and Danang districts.

The Plague Epidemic.

The mortality from plague has now sunk to a few hundreds weekly. Burma heads the list for the week ending July 7th with 243 deaths, the Punjab comes next with 155, the Bombay Province returned 149, Bengal 25, Mysore 19, United Provinces six, and Madras five. The latest destroyer of the rat flea is notified to be crude petroleum. This substance seems effective against the flea but has no power over the plague bacillus. One advantage it possesses is in its cheapness. It is of more importance, however, to kill the rat than the parasitic flea. In the Punjab the people have come to recognise the dangers attached to the rat and are killing these pests freely and of their own accord. In Bombay poison has been largely employed and about 200,000 rats are said to have been destroyed in the year. For this result over 1,000,000 baits were laid down. It is stated that a female rat will produce about 50 young each year, but upon this point more evidence is wanted. The periodicity of plague outbreaks has not yet been explained and it is not yet known whether this character is dependent upon conditions affecting the bacillus, the flea, or the rat.

The Spread of Cocaine Eating in India.

The habit of taking cocaine, which has produced such disastrous results in certain towns of India, is unfortunately spreading widely. Recently in the neighbourhood of Delhi and in certain native States the habit has been contracted, and the Punjab Government, following the example of the United Provinces and Burma, proposes local legislation to amend the Excise Act so as to get fuller powers of dealing effectively with the sale of this drug.

July 21st.

Medical News.

UNIVERSITY OF EDINBURGH.—The following is the official list of passes at the recent professional examinations for degrees in medicine and surgery:—

First Professional Examination.—T. A. Adams, Peter Allan, Alexander Archibald, O. H. Blacklay, Robina Blackwood, H. R. Borcherds, G. S. Brock, W. D. Brownrigg, Gilbert Burnet, J. le F. C. Burrow, Andrew Campbell, A. D. Campbell, T. F. Craig, W. A. Dunn, T. E. Evans, A. J. Ewing, M.A., A. G. Forbes, T. E. Forrest, A. S. Glynn, Christopher Gordon, G. M. Graham, A. L. Grant, Max Greenberg, J. D. Gunn, B.A., T. E. Harwood, B.A. (with distinction), John Hepburn, W. R. C. Heslop, D. van V. Hoffman, A. J. G. Hunter, C. C. Iles, G. L. W Iredale, W. D. Kirkwood, J. St. P. Knight, James Lamberton, J. P. Litt, J. M. Logie, F. R. Lucas, W. O. Lyons, D. J. M'Afee, W. V. Macaskie, H. J. M'Caw, A. E. P. M'Connell, Marion I. A. Macintyre, A. E. Mackenzie, J. M. Mackinnon, P. W. Maclagan, K. A. Maclean, Lorna D. M'Lean, William M'Naughton, N. F. Mann, A. M. Masters, S. N. Mokand, D. O. Monro, B. B. Morgan, A. A. Morison, D. M Morison, T. C. Murphy, J. M. E. Turnbull, V. A. Vijayakar, R. N. Wallace, W. H. te Water, W. C. Whiteside, and J. L. Masterman Wood.

FOREIGN UNIVERSITY INTELLIGENCE.—*Basle:* Dr. Gelpke has been recognised as *privat-docent* of Surgery; Dr. A. Labhardt as *privat-docent* of Midwifery and Gynæcology; and Dr. E. Oppikofer as *privat-docent* of Oto-Rhino-Laryngology.—*Bordeaux:* Dr. Denucé, *agrégé*, has been appointed Professor of the Surgical Diseases of Children in succession to the late M. Piéchaud.—*Christiania:* Dr. Kristian K. H. Brandt has been appointed to the chair of Medicine.—*Copenhagen:* Dr. S. Monrad has been appointed Lecturer in Children's Diseases. Dr. Erlandsen has been recognised as *privat-docent* of Internal Medicine.—*Göttingen:* Dr. His of Basle has accepted the invitation to succeed Professor Ebstein. Dr. Th. Lochte of Hamburg has been offered the chair of Forensic Medicine in succession to the late Dr. Stolper.—*Halle:* Dr. Friedrich Fromme has been recognised as *privat docent* of Midwifery and Gynæcology.—*Heidelberg:* Dr. Richard Werner has been recognised as *privat-docent* of Surgery. Dr. Völker has been granted the title of Extraordinary Professor.—*Kiel:* Dr. Ernst Ziemke of Halle has been appointed Extraordinary Professor of Forensic Medicine.—*Königsberg:* Dr. P. Stenger, *privat-docent* of Otology, has been granted the title of Professor.—*Leipsic:* Dr. Heinrich Klien has been recognised as *privat-docent* of Neurology and Psychiatry.—*Marburg:* Dr. Arthur Heffter of Berne has been appointed to the chair of Pharmacology.—*Montpellier:* Dr. Gervais de Rouville, *agrégé*, has been appointed Assistant Professor.—*Munich:* Dr. Ernst Heilner has been recognised as *privat-docent* of Physiology.—*Nancy:* Dr. Guilloz, *agrégé*, has been appointed Assistant Professor.—*Naples:* Dr. Giuseppe Evoli and Dr. Pasquale Pezzullo have been recognised as *privat-docenten* of Internal Pathology.—*Paris:* Dr. Albarran, *agrégé*, has been appointed Professor of the Diseases of the Urinary Passages in succession to M. Guyon. Dr. Thoinot, *agrégé*, has been appointed Professor of Forensic Medicine in succession to the late M. Brouardel.—*Prague (Bohemian University):* Dr. Haskovec, *privat-docent* of Neuropathology, Dr. Weigner, *privat docent* of Anatomy, and Dr. Srdinko, *privat docent* of Histology and Embryology, have been promoted to Extraordinary Professorships. (*German University*): The selections for the chair of Pathological Anatomy are—(1) Dr. Kretz of Vienna and Dr. Kaufmann of Basle (equal); (2) Dr. Dürck of Munich; and (3) Dr. Heinrich Albrecht, Dr. Anton Ghon, and Dr. Friedrich Schlangenhaufer, all of Vienna.—*Rome:* Dr. Salvatore Ottolenghi, Extraordinary Professor of Forensic Medicine, has been promoted to be Ordinary Professor.—*Rostock:* Dr. Otto Büttner, *privat-docent* of Midwifery and Gynæcology, has been granted the title of Professor.—*Strasburg:* Dr. Oscar Römer, *privat-docent* of Odontology, has been promoted to an Extraordinary Professorship. Dr. Wollenberg of Tübingen has accepted the invitation to the chair of Psychiatry. Dr. Ulrich, Extraordinary Professor of Ophthalmology, is retiring.—*Toulouse:* Dr. Cestan, *agrégé*, has been appointed Professor of Clinical Surgery.—*Turin:* Dr. Camillo Magnani has been recognised as *privat-docent* of Ophthalmology.—*Vienna:* Professor Benedikt, Professor Politzer, Professor von Stoffella, and Professor Winternitz are all retiring.—*Würzburg:* Dr. Martin Reichhardt has been recognised as *privat-docent* of Psychiatry.

VACATION SCHOOL AT PASSMORE EDWARDS SETTLEMENT.—This school, only open during the month of August, is now in the fifth year of its existence and has already found successful imitators at Stratford, Walworth, Camberwell, and Hoxton, whilst similar schools are being opened in Leeds, Hull, Sheffield, and Liverpool. The scheme, originally copied from the United States, is likely to spread, for one of the only clauses of the present Education Act which proved to be non-controversial gives permission to local authorities to open vacation schools and provide some financial support. In the case of this pioneer enterprise application forms are sent to 12 schools in the neighbourhood of the Settlement, which has a permanent building in Tavistock-place, and it is laid down very clearly that the object of the school is for those children who are unable to go into the country during the holiday month of the schools. Four years ago the number of children on the first day was 380; this year the number has risen to 950. The cost works out at 1*s.* 6*d.* per child per week, the chief expense being £226 for salaries for the director, 24 teachers, and two accompanyists. The discipline is excellent and the arrangements are cleverly perfected by making the children assemble every 35 or 70 minutes at the end of a lesson in a central courtyard, where each child knows his or her place and marches off with a fresh teacher to a change of play-work. The classes do not exceed about 30 boys or girls and there are morning and afternoon sessions for different children. Those who may have forgotten our previous notes on this subject should be reminded that these vacation schools are chiefly intended to teach children how to play, how to occupy themselves, and to provide some recreation other than that usually enjoyed in the London streets. But great care is necessary to prevent the demon of "nervous strain" being introduced and therefore all subjects of the usual school curriculum are strictly banished. The present course consists of carpentering, cardboard modelling, basket work, musical drill, organised games such as basket ball, gymnastics, dancing, singing, clay modelling, drawing, brushwork, doll dressing, knitting, story-telling, nature study, and housewifery, which includes the laying of a table, making beds, and washing a baby. Both boys and girls seem to love the cookery lessons, which include various methods of using up stale bread and cold meat, boiling vegetables, preparing lemonade, jam puffs, sausage rolls, rock cakes, scones, and plum dumplings, besides chopping suet, cleaning utensils and knives. Then there is the preparation for washing-day, washing and boiling white clothes, and ironing and folding aprons and kitchen cloths. For the smallest children there are ordinary kindergarten games, bubble blowing and sand digging, and, thanks to the Duke of Bedford many of these classes are held in the garden adjoining the Settlement. This year two new classes have been opened, one in which a shoemaker teaches boys how to cobble their shoes and the other in an open air gymnasium provided by the liberality of the Duke. We visited the class-rooms at the end of a hot day and were pleased to find the windows open and a complete absence of human odour. Among side shows visits are paid to the Zoological Gardens and sketches are there made of the animals from life; both sexes visit the swimming baths and the elder boys get instruction in cricket in the playground of one of the neighbouring council schools. It is obvious that much physical benefit is derived from this month's occupation and anyone who has witnessed the delighted keenness of the children and the enthusiasm of the teachers can hardly doubt the success of the endeavour. Mrs. Humphry Ward has so far been fortunate in securing the instructors who have more than one month's holiday in the year and can therefore afford time, as one of them expressed it, to renewed study of the life of children.

DONATIONS AND BEQUESTS.—The late Mr. Charles Thornton, barrister, has bequeathed £1000 to the London Hospital, £1000 to the Victoria Hospital for Children, Chelsea, and £500 to the After-care Association.

PRESENTATION TO A NURSE.—Lord Methuen, as chairman of the committee of management of King's College Hospital, recently accompanied a small deputation upon a visit to Miss K. H. Monk at Brighton, for the purpose of presenting her with a testimonial on her retirement from the post of sister-matron, after 23 years of service to the hospital. The testimonial consisted of a purse of money subscribed for by over 500 friends and past and present members of the committee and medical and nursing staffs of King's College Hospital.

LITERARY INTELLIGENCE.—As the result of investigations extending over a period of many years, with the aid of expert assistance, Sir Almroth E. Wright has written a book which Messrs. Archibald Constable will shortly publish, and which should have a marked effect on the results obtainable by all students using the microscope. The object of the book is to show how best to get from any class of instrument the highest degree of satisfaction in proportion to its range. The text of the book goes hand-in-hand with experiments and the work also contains a complete vocabulary of technical terms relating to the microscope.

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, AUGUST 1ST.

The Home Office and Anthrax.

IN the debate on the report stage of the Home Office vote some references were made to the numerous deaths from anthrax. Mr. GLADSTONE stated that the number of deaths in 1900 was 37; in 1901, 39, and in 1902, 38. There was a jump up in 1903 to 47, in 1904 to 50, and in 1905 to 59. This progressive rise was receiving the grave consideration of the Home Office. It had been suggested as a remedy that the imported wool which harboured the germs of the disease should be dealt with at the port of landing; but the wool was imported in large quantities, made up in bales, and to have it unpacked on landing would mean the placing of a very heavy tax on the trade. In the meantime, however, a special committee of investigation had been appointed in Bradford, with a Government subsidy, and he was informed that there were real hopes by means of a chemical process of a remedy being found. If, however, wool containing these spores in dangerous quantity did not yield to treatment the only remedy would be to exclude the wool altogether.

The Lunacy Commission.

Another subject raised on the same report was the position of the Lunacy Commission. Mr. G. J. COOPER urged that the number of Commissioners should be increased. The Board as at present constituted was unable properly to discharge its duties. There were six Commissioners, three barristers and three medical men. On the work of inspecting lunatic asylums they went in pairs, a legal member always accompanying a medical member. But if all the lunatics in the asylums were examined each pair of Commissioners would have to examine 39,943 in the year. It was physically impossible that they could do so and determine whether anyone was wrongly detained in an asylum. He further complained of the growing tendency to send aged people into asylums. In 1903–04 1445 people over 70 years of age were sent into asylums as lunatics who were merely suffering from senile degeneration. The whole of these people ought to have been kept in the workhouse. He had heard it stated that if the rich were treated as these poor people were one-third of the members of the House of Lords would die in a lunatic asylum. The knowledge of the essential nature of insanity and its causes was not much better to-day than it was a hundred years ago and until a more scientific investigation into the cause of brain disease was made there would be no better means of cure forthcoming. It would be well if the Home Secretary were to make inquiries as to the working of the receiving-house system which had been adopted by lunacy authorities in Scotland and in America.—Mr. GLADSTONE, in reply, pointed out that in regard to lunatic asylums he had a mere shred of responsibility. He passed the plans and sanctioned the estimates; the county councils built the asylums; the Local Government Board sanctioned the loans, and the Lord Chancellor appointed the Commissioners in Lunacy. An inquiry into the whole system of inspection, which was antiquated and absurd, was desirable. It should be borne in mind, however, that the Commission on the Feeble-minded was about to report, and that this report would deal with lunatic asylums, and when it was received the Government would consider whether any, and if so what, action was desirable.

Provision of Food for School Children.

Dr. MACNAMARA asked the President of the Local Government Board whether he could now give any information as to the working of the Local Government Board Order of May, 1905, respecting the coöperation of boards of guardians in the work of providing food for children in attendance at public elementary schools suffering from lack of food.—Mr. JOHN BURNS answered: The Local Government Board obtained from its inspectors some information on this subject in March last, from which it appeared that in some populous districts, such as the large Lancashire and Yorkshire unions, a good deal of work has been done under the Order, but that elsewhere the cases relieved under the Order had not been very numerous. In the eastern counties no relief under the Order had been found necessary except at Norwich. In Birmingham, shortly after the Order came into force, the guardians were informed by the local education committee that there were 2600 underfed children in the parish and that they were being supplied with free meals. Numerous applications were made by the head teachers to the relieving officers on behalf of children under their care, but when inquiries were made as to the circumstances of the parents of these children it was found that in many cases the guardians would not be justified in granting relief under the Order. The largest number of children on any one day to whom meals have been supplied by the guardians under the Order was 482. At Bristol the guardians made arrangements with the local education authority to obtain the assistance of a local society interested in the welfare of children. The first list sent in by the teachers specified 74 children as being underfed by reason of parental neglect, but inquiry by the relieving officers showed that only in one case would the guardians be justified in giving relief. Up to the end of January the names of 55 children were submitted as coming within the Order but in only 11 cases was relief given. Thus out of 129 applications only in 12 instances did the guardians feel justified in giving relief. In Cheshire, Salop, &c., 27 cases were relieved—viz., two at Birkenhead, three at Bucklow, eight at Congleton, four at Stoke-on-Trent, and ten at Wolstanton and Burslem. In several unions, however, voluntary funds were started and thus children were relieved and kept off the rates. At Derby there were 127 applications and 17 children were found to be underfed. In Nottingham there were 107 applications and 51 relieved. In Leicester there were over 400 applications but in no case was relief found to be necessary. In the township of Manchester 120 cases were relieved, about 380 in Chorlton, and many in Prestwich. The operation of the Order in Lancashire was mainly restricted to the neighbourhood of Manchester and Bolton. As regards the East and West Ridings of Yorkshire, there were 2586 cases in Bradford, 375 parents of 1073 children were notified that relief was given on loan, and 50 parents were proceeded against for recovery of the cost. Of the 2586 cases 1513 were fed by the guardians on behalf of the education authority which administered a fund raised by the mayor. In Leeds 500 cases were fed at the cost of a voluntary fund. 110 cases were fed at first in Hunslet but the number was afterwards reduced to 30. In Bramley the guardians fed 291 and a voluntary fund 2523 cases. In London, generally speaking, very few cases were relieved under the Order, but in some ordinary poor relief was granted and in others food was provided by school children's meals associations from moneys voluntarily contributed.

Tuberculosis in Ireland.

Mr. FETHERSTONHAUGH asked the Chief Secretary to the Lord Lieutenant of Ireland whether the Irish Government had directed its attention to the circumstance that the increase of tuberculosis in Ireland had followed on the increased use of low-class American bacon, believed by many people to be the flesh of tuberculous swine; and whether as there was no Government inspection of possibly tuberculous meat at the ports of entry he would consider the advisability of issuing a circular to the various public health authorities in Ireland, calling their attention to the danger to health arising from the consumption of meat infected with the bacilli of tuberculosis and the necessity for vigilance of their inspectors in preventing unsound meat from being exposed for sale.—Mr. BRYCE replied: The entire question of the importation of food, which affects the United Kingdom generally, has been under the consideration of the Government, and my right honourable friend the President of the Local Government Board has introduced a Bill dealing with the matter. I refer to the Public Health (Regulations as to Food) Bill, which is down for second reading on Oct. 23rd.

Report of the Royal Commission on Tuberculosis.

Mr. FIELD asked the President of the Local Government Board whether he could state when the report of the Royal Commission on Tuberculosis would be issued; and whether it was intended to make a definite statement regarding the communicability of bovine tuberculosis to man.—Mr. JOHN BURNS answered: The Royal Commission hoped that the report which it proposes to issue would have been published before the adjournment, but it now finds that it will not be practicable to issue it before October. It thinks that it is necessary to include in the appendix a larger amount of experimental detail than it anticipated and to confirm certain important facts by additional experiments which are still under observation. I understand that a definite statement on the communicability of bovine tuberculosis to man will be made in the report.

Poor-law in Ireland and the Medical Profession.

Mr. O'SHEE asked the Prime Minister what were the reasons why he declined to recommend the appointment of an Irish medical man on the Royal Commission on the Poor-law to fill the vacancy created by the death of The O'Conor Don, and whether, as the Irish medical profession was vitally concerned in the investigations of the Royal Commission so far as regards Ireland, he would reconsider the matter.—Sir HENRY CAMPBELL-BANNERMAN answered: I do not see my way to reconsider this matter in the sense desired by the honourable Member. The selection of members of Royal Commissions is governed by general considerations and in any fresh appointment that may be made to the Royal Commission on the Poor law the honourable Member may be sure that regard will be had to the Commissioner's qualifications for dealing with the Poor-law as it is administered in Ireland. It does not follow that because Irish Poor-law medical officers are interested in the inquiry the appointment of an Irish medical gentleman would necessarily be the most fitting to make.

THURSDAY, AUGUST 2ND.

Poor-law in Ireland and the Medical Profession.

Captain CRAIG asked the Chief Secretary to the Lord Lieutenant of Ireland whether, in view of the great importance of the subject to the whole of Ireland, he would see his way to reconsider his decision regarding the constitution of the Irish Poor law Commission and appoint to it an independent member of the medical profession who was thoroughly conversant with the whole principles, honour, and interests of the Poor-law medical profession in Ireland.—Mr. BRYCE replied: The honourable Member is under a misapprehension. No vacancy exists in the Irish Poor-law Commission, which has now practically completed its labours. The vacancy which the honourable gentleman has in mind is in the Royal Commission on the Poor-law for the United Kingdom, and, as to that, I would refer him to the reply given by the Prime Minister yesterday to the question of the honourable Member for West Waterford.

FRIDAY, AUGUST 3RD.

Sleeping Sickness.

Mr. CATHCART WASON asked the Under Secretary of State for the Colonies whether, in view of the fact of the sale of Government House at Entebbe, the ravages of sleeping sickness, the insufficiency of the water-supply, fever, and the general unsuitability of the district adjoining the lake, he would before expending public money in the erection of a new Government House consider the advisability of removing the seat of Government, temporarily at any rate, to the Kampala district where the tsetse fly and sleeping sickness are unknown; and whether he would, in view of the importance of the East Africa and Uganda Protectorates, endeavour to pay, himself, a visit to the country.—Mr. CHURCHILL answered: With regard to the first part of the honourable Member's question I would refer him to the reply which I gave to his question of July 19th. The Secretary of State is communicating with the Deputy Commissioner of Uganda and Dr. Moffat on the question of the desirability of removing the seat of Government in Uganda to Kampala and when their replies have been received the whole matter will be carefully considered in consultation with the Commissioner. With regard to the second part of the honourable Member's question I should particularly desire to pay a visit to the East Africa and Uganda Protectorates if the Secretary of State were to consider that I could be spared from my duties in the House of Commons. But in view of the occurrence of an autumn session I fear my wish is hardly likely to be realised this year.

SATURDAY, AUGUST 4TH.

The Government and Vaccination.

Answering a question raised in the general debate on the motion for the holidays Mr. GLADSTONE admitted that the law in regard to vaccination exemption certificates was not in a satisfactory condition. He should be glad to see it altered. The whole question of the administration of the Act of 1898 was under the consideration of the President of the Local Government Board.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

BOTHAM, R. H., M.R.C.S., L.S.A., has been appointed Certifying Surgeon under the Factory and Workshop Act for the Staindrop District of the county of Durham.

CRISP, JAMES ELLIS, M.R.C.S., L.S.A., has been re-appointed Medical Officer for the Lacock district by the Chippenham (Wiltshire) Board of Guardians.

HILL, WALTER JAMES, L.R.C.P. Lond., M.R.C.S., has been re-appointed Medical Officer of Health of Clevedon (Somerset).

HUGHES, PERCY T., M.B., C.M. Edin., D.P.H., has been appointed Medical Superintendent to the Worcester County Asylum, Barnsley Hall, Bromsgrove.

MACLEAN, ALICE W., M.B., Ch.B. Glasg., has been appointed House Surgeon at the Chorlton-upon-Medlock Dispensary, Manchester.

PHILLIPS, H. J., M.R.C.S., L.R.C.P. Lond., has been appointed Assistant Medical Officer to the London Open-air Sanatorium, Pinewood, Wokingham, Berks.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

BRIGHTON, SUSSEX COUNTY HOSPITAL.—Third House Surgeon, unmarried. Salary £50 per annum, with board and residence.

BRIGHTON THROAT AND EAR HOSPITAL, Church-street, Queen's-road.—Non-resident House Surgeon for six months, renewable. Salary at rate of £75 per annum.

BUXTON, DEVONSHIRE HOSPITAL.—Assistant House Surgeon. Salary £70 per annum, with apartments, board, and laundry.

CENTRAL LONDON THROAT AND EAR HOSPITAL, Gray's Inn-road.—Registrar (Honorary).

CHELTENHAM GENERAL HOSPITAL.—Junior House Surgeon, unmarried. Salary £80 per annum, with board and lodging.

CHESHIRE, CROSSLEY SANATORIUM, Delamere Forest.—Assistant Medical Officer. Salary £50 per annum, with board, apartments, and laundry.

CHESTERFIELD AND NORTH DERBYSHIRE HOSPITAL AND DISPENSARY.—Senior House Surgeon. Salary £120 per year, with board, apartments, and laundress.

COTFORD, TAUNTON, SOMERSET AND BATH ASYLUM.—Assistant Medical Officer, unmarried. Salary £140 per annum, with apartments, board, and attendance.

DEVONPORT, ROYAL ALBERT HOSPITAL.—Assistant Resident Medical Officer, unmarried, for six months. Salary at rate of £50 a year, with board, lodgings, and laundry.

DORCHESTER, COUNTY ASYLUM.—Junior Assistant Medical Officer, unmarried. Salary £140, rising to £180, with board, lodging, &c.

EAST LONDON HOSPITAL FOR CHILDREN AND DISPENSARY FOR WOMEN, Shadwell, E.—Medical Officer for the Casualty Department for six months, renewable. Salary at rate of £100 per annum, with luncheon.

EAST SUFFOLK AND IPSWICH HOSPITAL.—House Surgeon. Salary £50 per annum, with board, washing, and residence.

EGYPTIAN GOVERNMENT, MINISTRY OF EDUCATION.—Professor of Midwifery and Gynaecology. Salary £400 a year. Also Medical Tutor and Registrar to Kasr-el-Ainy Hospital. Salary £400 a year.

GORDON HOSPITAL FOR FISTULA, &c., Vauxhall Bridge-road, S.W.—Resident House Surgeon.

INVERNESS, NORTHERN INFIRMARY.—House Surgeon. Salary £100, with board, &c.

LIVERPOOL, DAVID LEWIS NORTHERN HOSPITAL.—Two House Surgeons and a House Physician. Salary £80 each per annum, with residence and maintenance.

LIVERPOOL INFECTIOUS DISEASES HOSPITAL.—Assistant Resident Medical Officer, unmarried. Salary £120 per annum, with board, washing, and lodging.

LONDONDERRY AND NORTH-WEST OF IRELAND EYE, EAR, AND THROAT HOSPITAL.—Honorary Surgeon.

MACCLESFIELD GENERAL INFIRMARY.—Junior House Surgeon. Salary £60 per annum, with board and residence.

MANCHESTER, ST. MARY'S HOSPITALS, Whitworth-street West, and Clifford-street.—House Surgeon. Salary £70 per annum.

MIDDLESEX HOSPITAL, W.—Second Assistant to the Director of the Bacteriological and Clinical Laboratories. Salary £100 per annum.

NEWCASTLE-ON-TYNE DISPENSARY.—Visiting Medical Assistant. Salary £160 per annum.

NEWCASTLE-ON-TYNE, HOSPITAL FOR SICK CHILDREN.—Assistant Honorary Surgeon.

NEWPORT AND MONMOUTHSHIRE HOSPITAL.—Junior Resident Medical Officer. Salary £70 per annum, with board, residence, and washing.

NORTHAMPTON GENERAL HOSPITAL.—House Physician, unmarried. Salary £90 a year, increasing to £100, with apartments, board, washing, and attendance.

OXFORD, RADCLIFFE INFIRMARY AND COUNTY HOSPITAL.—House Physician, House Surgeon, and Junior House Surgeon. Each for six months, and unmarried. Salary of two former at rate of £80 and of latter at rate of £40 per annum, with board, &c.

PRESTON ROYAL INFIRMARY.—Resident Medical and Surgical Officer, unmarried. Salary £130, with board, residence, attendance, and washing.

ST. HELENS COUNTY BOROUGH.—Assistant Medical Officer (female). Salary £160 per annum, rising to £200.

ST. PETER'S HOSPITAL FOR STONE, &c., Henrietta-street, Covent Garden, W.C.—Junior House Surgeon for six months. Salary at rate of £50 a year, with board, lodging, and washing.

SHEFFIELD ROYAL HOSPITAL.—Assistant House Surgeon, unmarried. Salary £50 per annum, with board and lodging.

SOUTHAMPTON, ROYAL SOUTH HANTS AND SOUTHAMPTON HOSPITAL.—Junior House Surgeon. Salary £60 per annum, with rooms, board, and washing.

STOCKPORT INFIRMARY.—Junior Assistant House Surgeon for six months. Salary at rate of £40 per annum, with board, washing, and residence.

STROUD GENERAL HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and washing.

WEST BROMWICH DISTRICT HOSPITAL.—Resident Assistant House Surgeon, unmarried. Salary £50 per annum, with board, residence, and washing.

WORCESTER COUNTY AND CITY ASYLUM.—Third Assistant Medical Officer, unmarried. Salary £130 per annum, with board, lodging, and washing.

YORK DISPENSARY.—Resident Medical Officer, unmarried. Salary £120 a year, with board, lodging, and attendance.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of a vacancy as Certifying Surgeon under the Factory and Workshop Act at Stanford-le-Hope, in the county of Essex.

Births, Marriages, and Deaths.

BIRTHS.

HAYWARD.—On August 2nd, at The Grange, Wimbledon, the wife of John A. Hayward, M.D., F.R.C.S., of a daughter.

MOON.—On August 5th, at High Beach, Victoria-parade, Broadstairs, the wife of E. G. Moon, M.R.C.S., L.R.C.P., of a daughter.

OSBORN.—On August 7th, at Ennismore House, Dover, the wife of Francis Arthur Osborn, of a son.

PASSMORE.—On July 31st, at Felbrig, Carshalton, Surrey, the wife of William Henry Passmore, M.R.C.S., L.R.C.P., of a daughter.

ROBERTS.—On July 23rd, at Sion Hill, Garstang, the wife of Henry Roberts, M.D. Brux., M.R.C.S. Eng., L.R.C.P. Lond., of a daughter.

MARRIAGES.

BAKER—MACKIE.—On July 26th, at Esher parish church, Captain W. Lincoln Baker, R.A.M.C., Aldershot, to Mary Yeats, elder daughter of the late T. Mackie, of Great Western Estate, Ceylon, and Mrs. Mackie, Lisleworth, Esher, Surrey.

ST. JOHN—NORBURY.—On August 1st, at the parish church, Eltham, by the Rev. Elphinstone Rivers, Vicar of Eltham, and the Rev. A. E. Robie, D.D., Headmaster of Eltham College, assisted by the Rev. A. G. Hodgson, M.A., Alexander Story St. John, L.R.C.P., M.R.C.S., of Eltham House, Eltham, youngest son of the late Colonel F. C. St. John, Indian Staff Corps, to Mabel Eleanor, third daughter of Inspector-General Sir Henry F. Norbury, K.C.B., M.D., F.R.C.S., R.N., Hon. Surgeon to the King, and of Lady Norbury, of St. Margaret's, Eltham.

DEATHS.

HUDSON.—On August 6th, at Cork-street, London, John Hudson, M.D., in his 83th year.

NORCOTT.—On August 4th, at Grosvenor hill, Wimbledon, William Doyle Norcott, M.R.C.S. Eng., aged 86 years.

RICHMOND. On August 7th, at 11, Vicarage-road, Handsworth, James Richmond, M.D., D.P.H.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

CONCERNING BODIE.

"DR." Bodie, who, like his fellow quack, "Professor" Richard, claims to cure the lame and the halt by electricity, has recently come within the clutch of the law. At the Bradford City police court on July 19th he was fined 2s. 6d. with 10s. costs, or seven days' imprisonment in three cases respectively, for having committed breaches of the Employment of Children Act, 1903. The prosecution was undertaken by the health committee of the Bradford corporation at the instigation of Dr. W. Arnold Evans, the medical officer of health. Of the three children, two said that they had gone on the stage to thank Bodie for having cured them. The third, John Moriarty, said that he had received 1s. on a Thursday night and 3d. on the following night. Inspector Smith said that this last boy apparently had electricity passed into his leg, after having the joint of his ankle broken down. He then walked off the stage. What Bodie's apparent "cures" mean was well shown in the course of the trial of a man named Ernest Miller, a cripple, who was sentenced at the Clerkenwell sessions on May 22nd to 18 months' hard labour for stealing. It came out in evidence that Miller used to pose as one of Bodie's cures, but after being "cured" one night he appeared as much worse the next night and was "cured" again.

As pertinent to the above case we see that Bodie brought an action against Mrs. Hudson of Leeds for slander in that she asserted at the annual meeting of the Leeds Invalid Children's Aid Society that Bodie had paid money to the parents of the children who had been taken to the Tivoli Music Hall for treatment. The jury returned a verdict for Bodie with one farthing damages. In the course of the trial Bodie's manager denied that money had ever been given to either parents or children for their attendance on the stage. We direct the manager's attention to the evidence of John Moriarty at the Bradford city police court given above.

Mr. Justice Grantham, in the course of the action for slander at Leeds, is reported as saying "that the question was whether anyone had the right to accuse him (Bodie) of being a rank impostor and absolute lying." We presume that Mr. Justice Grantham was not aware of the evidence given by the police at Clerkenwell sessions in May.

THE SEXUAL PROBLEM.

To the Editors of THE LANCET.

SIRS,—The interesting contribution in THE LANCET of July 28th, p. 259, on "Professor August Forel on the Sexual Problem" reminds me that Professor Forel, who is professor of psychiatry at Zürich University, has issued his views in book form, "Die Sexuelle Frage," published by E. Reinhardt, Munich, 1905. This book is a forcible contribution to the physiology of the relation of the sexes and of the evolution of an improved race which, although wholly opposed to the trend of English opinion, might be acceptable to those of your readers who read German and have had their curiosity whetted by the extracts given by you. I am, Sirs, yours faithfully,

Leyton, Essex, July 31st, 1906. N. CAMPBELL, M.B., D.P.H.

"NOBLESSE OBLIGE."

IN our last issue under this heading we quoted an appeal by the Honourable E. Pomeroy in which he remarked that "No Doctor has yet refused to Vaccinate with the stuff guaranteed pure by the Local Government Board." With fine impartiality the Honourable E. Pomeroy now in the *Morning Leader* of August 3rd and August 4th issues the appeal which we give below:—

To DOCTORS.—No. II.

Vaccination has never been defined (see "Jenner and Vaccination," by Charles Creighton, M.D.).

The stuff issued by the Local Government Board, and called Calf Lymph, Pure Calf Lymph, Glycerinated Calf Lymph, &c., is *not* guaranteed pure by the Local Government Board.

Some scores of London children are annually either impaired for life or put to death by vaccination with the stuff *not* guaranteed by the Local Government Board.

Will any London doctor refuse to operate with the stuff *not* guaranteed pure by the Local Government Board? It is difficult to see in what way the white liquid secreted by grown-up calves for the nourishment of their young fails to answer the desideratum of pure calf lymph. Will any London doctor make use of some such pure calf lymph as is suggested and provide the usual certificates? If so, will he kindly communicate with the Hon. E. Pomeroy, 6, Campden House Chambers, Kensington, W.?

The advertisement which follows in the *Morning Leader* of August 4th upon the Honourable E. Pomeroy's advertisement begins: "DEAREST.—What must you think—not knowing circumstances?" And, indeed, it is wonderful to watch the workings of the layman's mind, when he is on the war-path against the medical profession.

CONTAGION FROM PUBLIC TELEPHONES.

To the Editors of THE LANCET.

SIRS,—May I ask that in the interests of the public you will publish my recent experience as to the growing danger arising from the use of the common mouthpiece by promiscuous callers at public telephones And perhaps you will invite correspondence from medical men and others with a view to obtaining suggestions as to minimising this menace to the public health During the last week three people used our public telephone who were in no way fit to do so, and yet under present conditions it is impossible to prevent the risk which they convey to other users of the telephone. In one case a man evidently advanced in consumption, having a violent cough with expectoration, used the instrument and afterwards I found the mouthpiece damp with, I presume, his congealed breath Later in the week a lady called up her medical attendant from his call office, and from the conversation which ensued I gathered that her children were suffering from measles. I also had a case in which from the conversation heard there is no doubt the user came from a house infected with chicken pox.

I personally use a pad saturated with a disinfectant, and perhaps if attendants were to frequently wipe the mouthpiece with such a pad risk would be obviated.

I inclose my card in confidence, but ask that I be allowed to sign myself,

CALL OFFICE ATTENDANT.

London, August, 1906.

"NOT VERY GAY."

IN reference to the article entitled "The Humours of Country Practice" which appeared in THE LANCET of July 28th, p. 275, a correspondent writes to us to say that the word "gay" in the expression of the patient concerning the state of his bowels, "Not very gay, sir," may be connected with the provincial English word "gain" meaning "tolerable" or "fairly." He is correct in his surmise but the word "gay" is not that which has the meaning of "merry" but the Scots word "gey" which is both an adjective and an adverb and in its adverbial sense bears the meaning of "tolerably," "fairly," or "pretty." For example, "gey bad" means "pretty bad"—i.e., rather worse than "rather bad" and not so bad as "very bad." The expression "not very gay" would therefore mean "not very regular," or "they do not act much," or "not notably." Jamieson in his Scottish Dictionary gives one meaning of "gey" as "worthy of notice" and Murray, Oxford English Dictionary, under the same word, says "Cf. gain"—i.e., "gain" in the sense spoken of above.

DISEASE IN THE BRIDE'S CAKE.

To the Editors of THE LANCET.

SIRS,—Now that the filthy practice of inflating the cellular tissue of the calf and other animals is being once more publicly condemned, mainly on the grounds of the dissemination of tuberculosis, I should like to draw attention to the equally disgusting and filthy practice of blowing icing and other sweetstuffs upon bride's cakes and other ornamental pastry by means of tubes applied to the lips of the pastrycook. I have quite recently come across a case where the man was suffering from well-marked syphilitic disease of the mouth and throat.

I am, Sirs, yours faithfully,

Putney, S.W., August 2nd, 1906. A. S. MORTON, M.D. Durh.

A LID FOR OPENED CONDENSED MILK CANS.

WE have had submitted to us by Nurse Bennett, of 48, Agnes-street, Waterloo Station, London, a lid made of tin for covering condensed milk tins when opened to prevent access therein of flies and dirt. The plan is to cut the top of the milk can right off and fit on the tin cap which consists of a narrow band or collar of metal surmounted by a flat hinged lid. The shape of this lid resembles the usual illustration of a segment of a circle, the segment being soldered down on to the edge of the collar, the hinge being in the centre of the chord, and the remainder of the circle forming the moveable lid, exposing underneath a semicircular flange at a distance of a quarter of an inch from the edge. The nurse says that she has found it useful in the sick room, particularly when on night duty, to cover a glass or jug of milk or beef-tea. We think it quite desirable that drinks that are left standing a long time should be covered up, and think that for condensed milk cans the idea is particularly good. If the top of the milk can is cut off neatly close to the edge we see no difficulty likely to be caused by the flange on the under side of the lid.

A CURE FOR INEBRIETY.

A CIRCULAR is issued by the Scottish Hagey Institute, whose offices are at 107, West Regent-street, Glasgow, which gives an assurance that the treatment adopted by the institute will not only enable inebriates to become total abstainers but will benefit them in a variety of other ways. Everyone knows that it is not extremely rare for an inebriate to become a total abstainer for a time, but we are not at present so much concerned with the efficacy or otherwise of this "cure for inebriety" as with the audacious offer of a commission of three guineas to medical men introducing patients. The institute might, if it chose, send circulars to medical men explaining its system of treatment, thereby leaving them to advise their patients as they think fit, but it is quite another thing to attempt to bribe the medical advisers of inebriate patients into recommending the "cure" advertised by the institute. We would advise our readers to beware of persons who seek to push their wares in this fashion.

INSURANCE APPOINTMENTS.

To the Editors of THE LANCET.

SIRS,—I have just received a call from an insurance agent who said that the chief medical officer of the company he represented had given him my name and that of one other practitioner in this locality for an appointment, the salary of which was to be £100 per annum in addition to fees. It soon appeared, however, as indeed I had half expected, that the "qualification" for this valuable appointment was 500 shares in the company, which, by the way, was only registered last week!

I frankly told the young gentleman that I was too old a bird to be caught with chaff of that nature, but he was confident that plenty of my brother practitioners would jump at the chance.

I am, Sirs, yours faithfully,

Woolwich Common, August 8th, 1906. THEODORE MAXWELL.

CUSTOMS OFFICERS AND THE PUBLIC HEALTH.

THE Commissioners of His Majesty's Customs, in their report for the year ending March 31st last, remark that the officers of Customs are employed in various ways for the security of the public health, a fact which has largely escaped the notice of the public Duties directly connected with the public health are performed not only under the Public Health Act, 1875, as amended by the Public Health Act, 1896, but also under Section 5 of the Revenue Act, 1883. Under this latter Act all ships on arrival at any port or place in the United Kingdom must bring to at the station appointed for the boarding of ships and it is at this time that the duties of the Customs department under the Acts mentioned are performed. The procedure is briefly as follows. The master or other responsible officer is questioned as to where the vessel comes from and as to whether there is, or has been, any sickness on the voyage These questions are answered either verbally or in writing, as circumstances require. If the replies are satisfactory the vessel is allowed to proceed. If, however, they show the vessel is infected she is required to moor at a specified place and cannot quit it nor can any person leave her until an examination is made by the port medical officer. A vessel is deemed "infected" when she has, or has had, on board any case of cholera, yellow fever, or plague. In cases where there has been on board during the voyage any other illness calling for the intervention of the port medical officer he is so informed before any person leaves the vessel. Persons making false answers to the oral or written questions or wilfully neglecting or refusing to obey or carry out, or obstructing the execution of, any regulations framed under the Public Health Act are liable to heavy penalties. In September last a vessel arrived at an east coast port with a suspected case of cholera on board. She was accordingly required to moor at the mooring station appointed for infected vessels. Upon examination by the medical officer it turned out that the patient was really suffering from the effects of excessive drinking and, upon the certificate of the medical officer that the vessel was free from infection, she was allowed to proceed.

HARVEST BUGS.

To the Editors of THE LANCET.

SIRS,—I should be glad if any of your readers could tell me of a reliable remedy for getting rid of the "harvest bug" I have tried sulphur ointment and corrosive sublimate lotion but without any relief. The irritation, more especially at night, is almost unbearable.

I am, Sirs, yours faithfully,

L.R.C.P.

August 7th, 1906.

COMMUNICATIONS not noticed in our present issue will receive attention our next.

Ormond-street (2.30 P.M.).

FRIDAY (17th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), Guy's (1.30 P.M.), Middlesex (1.30 P.M.), Charing Cross (3 P.M.), St. George's (1 P.M.), King's College (2 P.M.), St. Mary's (2 P.M.), Ophthalmic (10 A.M.), Cancer (2 P.M.), Chelsea (2 P.M.), Gt. Northern Central (2.30 P.M.), West London (2.30 P.M.), London Throat (9.30 A.M.), Samaritan (9.30 A.M. and 2.30 P.M.), Throat, Golden-square (9.30 A.M.), City Orthopædic (2.30 P.M.), Soho-square (2 P.M.), Central London Throat and Ear (2 P.M.), Children, Gt. Ormond-street (9 A.M., Aural, 2 P.M.), St. Mark's (2.30 P.M.).

SATURDAY (18th).—Royal Free (9 A.M.), London (2 P.M.), Middlesex (1.30 P.M.), St. Thomas's (2 P.M.), University College (9.15 A.M.), Charing Cross (2 P.M.), St. George's (1 P.M.), St. Mary's (10 P.M.), Throat, Golden-square (9.30 A.M.), Guy's (1.30 P.M.), Children, Gt. Ormond-street (9.30 A.M.).

At the Royal Eye Hospital (2 P.M.), the Royal London Ophthalmic (10 A.M.), the Royal Westminster Ophthalmic (1.30 P.M.), and the Central London Ophthalmic Hospitals operations are performed daily.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

MONDAY (13th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith road, W.).—12 noon: Lecture:—Dr. Low: Pathological Demonstration. 2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: X Rays. Operations. Mr. Dunn: Diseases of the Eye.

TUESDAY (14th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—2 P.M.: Medical and Surgical Clinics. Diseases of the Throat, Nose, and Ear. 2.30 P.M.: X Rays. Operations. Dr. Abraham: Diseases of the Skin.

WEDNESDAY (15th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: Diseases of the Throat, Nose, and Ear. Dr. Saunders: Diseases of Children. 2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: X Rays. Operations.

THURSDAY (16th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: X Rays. Operations. Mr. Dunn: Diseases of the Eye. 4 P.M.: Lecture:—Mr. Dunn: Demonstration on Selected Eye Cases.

FRIDAY (17th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—2 P.M.: Diseases of the Throat, Nose, and Ear. Medical and Surgical Clinics. 2.30 P.M.: X Rays. Operations. Dr. Abraham: Diseases of the Skin. 5 P.M.: Dr. Ball: Some Points in Middle Ear Suppuration (with lantern slides).

SATURDAY (18th).—POST-GRADUATE COLLEGE (West London Hospital, Hammersmith-road, W.).—10 A.M.: *Diseases of the Throat*, Nose and Ear. 2 P.M.: Medical and Surgical Clinics. 2.30 P.M.: X Rays. Operations.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

THE Index to Vol. I. of 1906, which was completed with the issue of June 30th, and the Title-page to the Volume, were given in THE LANCET of July 7th.

VOLUMES AND CASES.

VOLUMES for the first half of the year 1906 are now ready. Bound in cloth, gilt lettered, price 18*s*., carriage extra.

Cases for binding the half-year's numbers are also ready. Cloth, gilt lettered, price 2*s*., by post 2*s*. 3*d*.

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will insure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD.	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and Agents are authorised to collect, and generally do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address—THE MANAGER, THE LANCET OFFICES, 423, STRAND, LONDON, ENGLAND.

Communications, Letters, &c., have been received from—

A.—Dr. F. W. Alexander, *Lond.*; Dr. J. M. Atkinson, Chadwell Heath; Messrs. W. J. Andrews and Son, Bristol; Anderson's College Medical School, Glasgow, Secretary of; Mr. J. W. Arrowsmith, Bristol; Messrs. Armour and Co., Lond.

A Lecture

ON

THE TREATMENT OF CANCER OF THE STOMACH.

Delivered at the Medical Graduates' College and Polyclinic on June 27th, 1906,

BY A. W. MAYO ROBSON, D.SC., F.R.C.S. ENG.,

HONORARY SURGEON TO THE DREADNOUGHT HOSPITAL.

GENTLEMEN,—When it is realised how frequent gastric cancer is and that the disease is at first local and curable in a considerable proportion of cases by early removal, it is curious that the surgical treatment of this disease has not yet received more attention. The explanation of this anomaly can only be ignorance or prejudice, for clinical experts, both medical and surgical, in various parts of the world, have for some years not only been writing on the subject and trying to convince the profession and the public of the needs and the possibility of an early diagnosis with a view to successful radical treatment, but they have also clearly demonstrated the possibility of successfully practising what they have preached both with regard to diagnosis and treatment.

As regards the frequency of carcinoma of the stomach, Dr. O. N. Dowd[1] called attention to the fact that according to the census reports, there were no less than 9000 deaths from cancer of the stomach in the United States in 1900 and of these very few had been submitted to surgical treatment. I find on referring to the Registrar-General's report for England and Wales that during the years 1901–04 no less than 19,607 deaths from cancer of the stomach were registered, equal to 4901 per annum.

Our ignorance with regard to the possibility of an early diagnosis is partly true, for in 5 per cent. of cases the disease runs its course without any local signs, but if it were fully recognised that we have in exploratory incision the one diagnostic resource which is reliable in a considerable proportion of cases of incipient cancer this reproach might be put away. On this matter prejudice stands in the way, for although there may not be a difficulty in convincing a patient of the desirability of operation when a disease is positively diagnosed, for instance, when a tumour has made the diagnosis almost certain, yet when an operation is suggested as a means of diagnosis the patient is by no means so easily convinced of the desirability of accepting even a slight risk, especially if the medical attendant does not himself feel the absolute necessity of pressing the importance of the procedure. In blaming the public for the delay I think we are often unjust to their intelligence, for persons of ordinary intelligence can, as a rule, easily be made to understand that the waiting for a positive diagnosis means standing idly by until progressive involvement means hopeless extension of the disease.

Whenever a patient near or over 40 years of age complains of loss of appetite and other gastric symptoms, particularly pain and vomiting, followed by loss of flesh and strength, especially if associated with anæmia, and if the symptoms fail to yield in a short time to proper treatment, cancer of the stomach should be suspected, and if repeated examinations of the stomach contents after test meals show diminished digestive power and impaired motor function with possibly a diminution of free hydrochloric acid and the presence of lactic acid, an exploratory operation ought to be urged without delay in order to complete the diagnosis and if necessary to carry out curative treatment.

Laboratory methods.—The chemistry of the gastric secretion, the microscopic findings in the stomach contents, and the examination of the urine, fæces, and blood, all of which are of value in the later stages of the disease, must not have too great a weight attached to them in the earlier stages, nor must the clinician wait for the development of tumour or glandular enlargement before recommending exploratory incision.

Since cancer *per se* has no symptoms, it not infrequently happens that if the growth involves the body of the stomach and not the orifices, it may pursue its complete course without giving rise to any definite local symptoms and it has not infrequently happened that the cause has only been discovered at the necropsy. This form of latent cancer constitutes 5 per cent. of all cases according to Professor W. Osler, who also gives it as his opinion that 10 per cent. of all cases of cancer of the stomach run an extremely rapid course, terminating in death within three months.

In no less than 59·3 per cent. of cases of cancer of the stomach on which I have performed gastro-enterostomy for the relief of symptoms, the disease having advanced too far for gastrectomy, the long history of painful dyspepsia suggested the possibility of ulcer preceding the onset of malignant disease. W. J. Mayo, in 157 cases of cancer of the stomach, found a previous history of ulcer in 60 per cent. Cruveilhier discussed the cancerous transformation of ulcer of the stomach in 1839, but to Dittrich, writing in 1848, belongs the chief credit for drawing attention to the subject. He described in 160 cases of new growth six cases of cancer developing in the immediate vicinity of active or healed ulcers, two cases of the association of cancer and ulcer, and two cases in which the cancer was limited to a certain part of the margin of the ulcer, the rest remaining sound. Brinton in 1856 recognised the possibility of the grafting of cancer upon long-standing ulcer. Lebert in 1878 considered that the cancerous transformation occurred in 9 per cent. of ulcers but Zenker in 1882 expressed a strong opinion that all cases of cancer of the stomach were secondary to ulceration.

If these conclusions that ulcer is a predisposing cause of cancer are correct, and my experience tells me they are, then it is quite clear that we must in all cases in which an ulcer of the stomach resists treatment or its scar narrows the pylorus recommend an early gastro-enterostomy or excision of the ulcer in order to prevent the development of carcinoma. If a gastro enterostomy has been performed then the mechanical irritation by food of the ulcer in the pyloric region is reduced and the friction necessary to produce a carcinoma will probably not occur.

The origin of carcinoma in an ulcer of the stomach is only another instance added to many of which we have knowledge of the effect of persisting irritation in establishing malignant changes. Carcinoma occurs most frequently in those areas in which the ulcers chiefly lie. Whatever the frequency of the malignant change in chronic ulcer may prove to be the fact of its occurrence should be an additional incentive to the earlier surgical treatment of ulcers which prove rebellious.

Medical treatment may be considered in a few words; it cannot cure and can do very little even to prolong life; it therefore applies only to cases too advanced for surgical treatment or where operation is declined. It aims at nourishing the patient as much as possible and at relieving pain or other symptoms as they arise.

Surgical treatment offers the only chance of relief and the only possible chance of cure and in order that the best results may be attained the physician and surgeon must act in concert, so that by a timely diagnosis an operation may be undertaken at the earliest possible date. There is ample evidence to show that for some length of time cancer is a purely local disease; and, just as in the breast, the tongue, and the uterus we can point to patients living comfortably years after the removal of the disease, so in gastric cancer it is reasonable to assume, and in fact can now be proved by positive evidence, that a like result may be brought about. Here, however, we are faced with the difficulty of a sufficiently early diagnosis being made, and it is not only necessary for us to appeal for an early, exhaustive, and persistent investigation into suspicious stomach cases, but that when suspicion arises an early surgical consultation may be held, and, if needful, an exploratory operation carried out to complete the diagnosis. Let us remember, also, that to prolong the investigation uselessly and to wait until a tumour develops into a recognisable quantity, is to lose the favourable time for a radical operation; for although a clinical examination of the patient may give us strong grounds for suspicion, our diagnosis can only be rendered certain by a digital examination, which may be effected through a small incision that can, if needful, be made under cocaine anæsthesia with little, if any, risk. At the time of the exploratory procedure it will be generally advisable to have everything ready to follow it up by whatever further operation may be called for. It may be discovered that the disease is manifestly not malignant and that no further operation is necessary, in which case the patient and his friends will be relieved of their anxieties. Or it may be found that some curative operation can be done, for instance, the removal of adhesions or the relief of obstruction. Or it may be discovered that the disease resembles malignancy both in its history and physical signs and in the form of the tumour, which on account of extent and adhesions and from the presence of enlarged glands it seems impracticable to remove with any hope of permanent success. The results of drainage by gastro-enterostomy in some of these cases, which at the time appeared beyond cure, are remarkable. The following is an example, one of many such cases on which I have operated and in which the patients were at the time of operation extremely ill and supposed to be suffering from cancer of the stomach but who, as the result of surgical treatment, are in good health years later.

---

[1] Medical Record, 1905.

The patient, a medical man, aged 31 years, had had dyspepsia for 17 years; this had been more severe during the last 20 months. 16 months previously vomiting began and from the outset large amounts were vomited but never contained blood. In December, 1897, the stomach reached to the pubes and visible peristalsis was present. Relief followed dieting and lavage until March, 1898, since which time the pain had been almost constant. A loss of weight had occurred from 10 stones to 8 stones 6½ pounds and the patient was extremely feeble. Operation was performed on May 6th, 1898, when a large irregular tumour was found at the pylorus and along the lesser curvature with extensive adhesions, but the glands, though large, were discrete. *Gastro-jejunostomy was followed by relief of all symptoms.* When the patient left the nursing home on June 7th his weight was 8 stones; on August 17th, 1898, it was 9 stones 3 pounds. The following is an extract from a letter from the patient, dated Feb. 12th, 1900: "My health continues perfect. I have not lost a day's work through illness since I recovered." He is in good health in 1906, eight years after operation.

I would lay particular stress on this class of cases, for I think it serves to explain some misconception about cancer generally. It would be easy for anyone to raise a claim to having cured a number of cases of cancer of the stomach by gastro-enterostomy, but I do not for a moment believe that any of these cases were more than inflammatory tumours formed around chronic gastric ulcers; nevertheless, I have no doubt that they would have proved fatal just as certainly as if they had been cancer had no operation been done. I feel sure that many such would have been certified as deaths from cancer of the stomach had no exploration been done or no necropsy and microscopic investigation made.

The cases also illustrate another point. Even though a tumour be present, and even though it be probably too large for removal, it may be quite worth while advocating an exploration, to be followed up by gastro-enterostomy if that be practicable, in the hope that the disease may prove to be wholly or partially inflammatory, which the physiological rest assured by gastro-enterostomy will either cure or materially relieve.

To pass to the genuine cancer cases, What can we do for them? This will depend (1) on the position of the growth; (2) on its extent; (3) on the presence of adhesions; and (4) on glandular invasion or secondary growths.

First as to position. In irremoveable growth at the cardiac end, if it involves the cardiac orifice and adjacent portion of the stomach, gastrostomy or jejunostomy should be performed in order that starvation may be staved off The view that gastrostomy is both a dangerous and useless operation is, I know, held by some, but I feel convinced that such views are mistaken ones. When these cases, either of cancer of the cardiac end of the stomach or of the œsophagus, were handed over to the surgeon in a moribund condition the mortality of gastrostomy was, of course, terrible, and the short survival, even if successful from an operative point of view, made the procedure almost useless; but when one can point to a series of nearly 30 gastrostomies performed since 1897 with only a 5 per cent. mortality and great prolongation of life to many, there are good grounds for saying that the operation is well worth doing. The operation is quite a simple one and, if necessary, can be performed under cocaine anæsthesia in a very short time In several cases the patients have lived a year or more and have gained considerably in weight, even up to 1½ stones and have lost their pain and the distressing sense of starvation.

The second class of cases to be considered is where the disease involves the pylorus and is producing obstruction to the passage onwards of the gastric contents, but where on account of extensive adhesions, secondary growths, or involvement of glands, it is considered unwise to attempt pylorectomy or partial gastrectomy, though there is sufficient free stomach wall left to enable a gastro-enterostomy to be performed. In such cases a gastro-enterostomy, if performed with proper expedition and adequate precautions, affords the greatest relief to the sufferer who not only loses the distress due to painful peristalsis and to the irritation of retained secretion but also becomes freed from the toxæmia due to absorption of the poisonous fermenting stomach contents which are drained away into the intestine and there disposed of. Thus life is prolonged and made more comfortable, flesh and colour are regained, and even in cases of cancer the patient may have a new lease of life.

The following cases are examples:—

CASE 1.—The patient, a man, aged 36 years, was seen on Oct. 26th, 1901. He suffered from manifest tumour of the stomach and had a history of stomach trouble extending over several years, with vomiting of blood and passage of melæna on two occasions within the preceding four months. At the operation a large tumour involving the duodenum and pyloric end of the stomach, too adherent for removal, was found and gastro-enterostomy was performed. After the operation he went abroad and for six months he rapidly gained weight and felt very well. He then began to get thinner and lose strength and without any pain he gradually became weaker and succumbed in September, 1902, 11 months after operation.

CASE 2.—The patient, a man, aged 63 years, had had symptoms for five years; at first those of chronic ulcer, later those of malignant ulcer with tumour associated with hæmatemesis. Gastro-enterostomy was performed on March 22nd, 1901. He made a good recovery and returned home at the end of the month, having gained about 4 pounds in weight during the fourth week. He ultimately gained about 2 stones and lived for a time in great comfort, but the growth progressed and he succumbed to exhaustion about a year later, having been able to enjoy life for some months.

CASE 3.—The patient, a man, aged 68 years, was operated upon on July 18th, 1902, for pyloric tumour with dilatation of the stomach. He was extremely feeble and suffering great pain. The disease appeared to be cancer and the glands were extensively involved, so that gastro-enterostomy only could be performed. A letter from Dr. S—— says that the patient gained 10 pounds up to November and is now 14 pounds heavier than before he fell ill. He is able to take regular exercise and has never felt any pain after taking any meal whatever since the operation. He was well over three years later.

In some cases where the condition of the patient and not simply the extent of the growth has prevented a radical operation, the speedy restoration to health enables a radical operation to be subsequently undertaken. The following case, out of others that could be cited, serves to illustrate what I mean. The patient, a man, aged 62 years, had had symptoms for a year. An epigastric tumour had been noticed for a month. There was no free hydrochloric acid in the vomit. An exploratory operation was performed on Nov. 15th, 1900. A ring of cancer was found forming an hour-glass-shaped stomach. The patient was too ill for gastrectomy. Posterior gastro-enterostomy was performed. A good recovery followed. On Dec. 20th, a month later, partial gastrectomy was performed, the ring of growth being removed and the cardiac and pyloric remnants of the stomach being fixed together over a large bone bobbin. A good recovery again resulted and the patient returned home within the month. He was quite well a year later. A letter was received from Dr G—— in November, 1902, in which it was stated that the patient had put on flesh, had gained colour, and had been able to take food well for over a year, but had succumbed to exhaustion from secondary growths in the omentum on March 30th, 1902 about 18 months after operation.

These examples will suffice to show the beneficial effects of gastro-enterostomy even in advanced cases of cancer of the stomach, for, as will be seen immediately, it is only in the cases too advanced for removal that the short-circuiting operation should be performed.

With regard to these patients the question may be asked, Is a palliative operation worth while? I have no hesitation in answering this decidedly in the affirmative, for in cases where cancer of the pylorus is obstructing the outlet of the stomach, the painful peristalsis, frequent vomiting, and inability to take food can all be relieved, and the remainder of life, months or years as the case may be, can be rendered not only tolerable but comfortable, for food can be taken in safety and enjoyed, the pain due to peristalsis disappears, the vomiting ceases, and the patient frequently puts on flesh considerably and is enabled to resume his duties, death ultimately occurring from exhaustion. The operation can be done with little risk, as including all my cases of posterior gastro-enterostomy performed during the past ten years the mortality is only 3·3 per cent., a great contrast to the death-rate of these cases a few years ago.

The third class of cases is of great interest and includes those where the disease is limited to the stomach and where the lymphatic glands and adjoining organs have not been seriously invaded, the patient being in a sufficiently good condition to permit of the radical operation being done. The following are examples.

CASE 1.—The patient, a woman, aged 50 years, had had symptoms for five months and a tumour had been noticed for three weeks. An operation was performed on Jan. 31st, 1901. The tumour was found to be involving the whole circumference of the pyloric end of the stomach, a short distance from the pylorus. After the growth had been widely excised the distal and proximal ends of the stomach were brought together over a large bone bobbin. The glands were excised from the lesser and also from the greater omentum. A smooth recovery followed. On Jan. 4th, 1903, two years later, her medical attendant wrote to tell me that the patient was remarkably well and that there was no sign of recurrence. She remained well until 1905, over four years, when there was recurrence of the disease.

CASE 2.—In the case of this patient, a woman, aged 54 years, there had been loss of flesh, and pain, with failing health for eight months, and slight jaundice and a tumour in the epigastrium and right hypochondrium for a shorter period. An operation was performed on August 9th, 1900. The gall-bladder, containing gall-stones and the site of a tumour, was removed. As the adjoining portion of the liver was involved a wedge-shaped partial hepatectomy was performed and as the pylorus was also the site of growth a partial gastrectomy including the pylorus was done, the cut section of the stomach being united to the duodenum by two continuous sutures over a bone bobbin. The removed tumour, examined microscopically after operation, proved to be cancer. That part of the abdominal wall to which the tumour had been adherent was also excised. The patient was reported to be well in 1905.

CASE 3.—The patient, a middle-aged man, who had been ailing for a year and had had stomach symptoms for three months and a noticeable tumour for six weeks, was supposed to be too ill and anæmic for operation, but as the tumour, which was situated in the left hypochondrium and epigastrium was freely moveable, I decided to operate. On May 23rd, 1902, I found a mass of cancer involving the centre of the stomach, which I removed along with some glands adjoining it. Recovery was uninterrupted. A letter dated Jan. 22nd, 1903, from his medical attendant contained the following statements: "Patient very well, has gained 14 pounds in weight. No evidence of return of growth. Able to transact his business." The patient lived until June, 1906, over four years after operation.

CASE 4.—In 1902[2] I reported a case *in extenso* where I had removed the whole of the stomach, except a small portion of the dome adjoining the œsophagus, for malignant disease, on March 18th, 1901. I am glad to say that this patient, over five years later, remains in absolutely good health; he has a good appetite, enjoys his food, and is able to attend to his business as usual.

These cases will be sufficient to show that removal of even a considerable portion of the stomach may be something more than a palliative operation; and I think it justifies me in saying that although it is better to have cases of cancer diagnosed and operated on early, yet we need not take the pessimistic view that if a tumour be manifest it is too late to perform a radical operation.

The fourth class of cases is that in which the disease involves a great part or the whole of the stomach, the disease being irremoveable and gastro-enterostomy impracticable, and in which any attempt at taking food brings on pain and vomiting, so that the patient unless relieved must rapidly die in great distress; here a jejunostomy can be performed by a very simple and similar procedure to that of gastrostomy and through a Jaques catheter sufficient food can be given to ward off starvation and relieve the pain caused by attempts at taking food by the mouth. This operation can be done through the small exploratory incision and need involve very little longer time. It may prolong life for months or even for a year and make the end much easier and certainly less painful. I reported a case of jejunostomy in 1891 in which the patient lived three months, and in 1904 one by a new method that had lived for 12 months after jejunostomy, and the fact of my case of almost complete gastrectomy being well five years after operation shows that the passage of food directly into the small intestine may be compatible with a comfortable life. Although the operation is rarely called for it is one nevertheless which should be borne in mind, as in an appropriate case it may confer a great boon upon the patient and render tolerable an otherwise comfortless existence.

No useful purpose can be served by comparing the results of gastrectomy with those of gastro-enterostomy for cancer, since the latter operation in malignant disease is reserved for late cases that have passed the stage when gastrectomy would have been a justifiable operation; nor do I consider that an estimate of the true value of gastrectomy can be attained by a consideration of the earlier cases operated on before the technique had been perfected. Up to the end of 1905 Kocher had performed 110 partial resections of the stomach, with a mortality of 24 per cent., but of the cases, 58 in number, operated on since 1898 the mortality was only 15 per cent., a percentage closely corresponding to that of the brothers Mayo, who up to the end of last year had performed 100 gastrectomies with a mortality of 14 per cent. In my own practice since 1896 the mortality for partial gastrectomy has been 16 per cent., and Maydl's statistics give also a 16 per cent. mortality. We may thus conclude that the immediate risks of partial gastrectomy as calculated from a considerable series of cases are between 14 and 16 per cent. Of the 27 cases of total gastrectomy collected from all sources by Mr. H. J. Paterson[3] ten patients died, a mortality of 36 per cent. Of the 20 cases of sub-total gastrectomy six patients died, a mortality of 30 per cent.

The remote results are equally interesting and not less important, not only from the point of freedom from recurrence but also as to the effect on the general health and comfort of the patient after the removal of the whole or part of the stomach. I have had under my notice for over five years a case of sub-total gastrectomy and from observations on this case it would seem as if the whole of the functions of the stomach could be replaced.

It would at first sight appear that as a reservoir the stomach could not be replaced, but the fact that a meal of moderate size can be taken shows that the upper end of the duodenum or the lower end of the œsophagus or both become dilated and serve that purpose, though perhaps to a limited extent. The mechanical functions of the stomach can be vicariously performed by the mouth aided by a careful selection of diet. The digestive functions of the stomach can be taken up by the pancreatic and the intestinal secretions and the absorption which normally occurs in the stomach can as easily take place in the small intestine. Pachon and Carvalho[4] have shown that dogs may gain in weight and remain in perfect health after removal of the entire stomach, and further observations on patients after complete gastrectomy, as in Schlatter's case, show that perfect health is compatible with an absence of the stomach.

Of the 27 total gastrectomies it is interesting to note that ten patients are living and well 8, 7, 5, 4½, 4, 3½, 2, and 1¼ years, and two others at less periods, after operation, while others survived 3¼ years, 1¼ years, 13 months, 9 months, and 7 months respectively. With regard to sub-total gastrectomies, of the 14 patients who recovered from operation one was well 7½ years, one 6¼ years, and one 5¼ years after operation; while of the others one survived operation for 11 years and died from heart trouble without recurrence, one

it. Med. Jour., Nov. 8th, 1902.

[3] THE LANCET, March 3rd, 1906, p. 574.

[4] Comptes Rendus de la Société de Biologie, 1905, p. 794.

5 years, two 2¾ years, two 1¾ years, and one 1½ years respectively.

The immediate results of partial gastrectomy have been mentioned above and the final history has been obtained by Mr. Paterson in 55 of those that recovered. Of the 55 patients 35 have died since the operation; one died from recurrence seven years, and two five years later, but it is interesting to note that all the other patients in whom recurrence ensued died within 3½ years, so that if a patient remains free from recurrence for four or more years there would seem to be a strong probability of cure. Eight of the patients who died, lived over 3 years after operation and the average duration of life in cases where recurrence took place was just over 2 years. Of the patients who are apparently cured, one is alive and well 14 years, one 7½ years, two 6 years, one 5½ years, two 5 years, five over 3 years, and three over 2 years subsequent to operation, and one was living 4½ years after operation, but recurrence was feared. Thus nearly 14 per cent. of the patients who recovered from operation would seem to be cured or to have a reasonable prospect of remaining free from recurrence.

In conclusion, I hope I have advanced sufficient evidence to prove the following:—1. How desirable it is to make an early diagnosis of cancer of the stomach in order that a radical operation may be performed at the earliest possible moment 2. That it may be needful to perform an exploratory operation in order to complete or confirm the diagnosis. 3. That such an exploration may be done with little or no risk in the early stages of the disease. 4. That even where the disease is more advanced and a tumour perceptible, an exploratory operation is, as a rule, still advisable in order to carry out radical or palliative treatment. 5. That where the disease is too extensive for any radical operation to be done, the palliative operation of gastro-enterostomy, which can be done with very small risk, may considerably prolong life and make the remainder of it much more comfortable and happy. 6. That some cases, thought at the time to be cancer, too extensive for removal, may after gastro-enterostomy clear up completely and get quite well. 7. That in cases of disease of the cardiac end of the stomach too extensive for removal, the operation of gastrostomy may considerably prolong life and prove of great comfort to the patient by preventing death from starvation. 8 That even where the disease is too extensive either for removal or for a gastro-enterostomy being performed with a fair chance of success, the operation of jejunostomy may prove of service to the patient. 9 That where a radical operation can be performed the thorough removal of the disease may bring about as much relief to the patient as does the operation for the removal of cancer in the breast, uterus, and other organs of the body, and that in some cases a complete cure may follow.

THE PUBLIC SUPPLY OF PURE OR SPECIALLY PREPARED MILK FOR THE FEEDING OF INFANTS.[1]

BY G. F. McCLEARY, M.D. CANTAB., D.P.H.,

MEDICAL OFFICER OF HEALTH OF HAMPSTEAD.

AMONG the newer measures for the prevention of infantile mortality which have been increasingly adopted by sanitary authorities during the last few years the public supply of specially prepared infants' milk takes a prominent place. Since the first British Infants' Milk Depôt was established by the St. Helens corporation in 1899 the number of these institutions has steadily increased, and we are now in possession of a fund of information relating to their work which was not at the disposal of the earlier workers in this movement. My own experience of the practical working of a milk depôt during a period of nearly four years has led me to think that the methods upon which the British milk depôts are generally conducted might with advantage be modified and extended, and that the time has now arrived when the whole question of the public supply of infants' milk should be thoroughly reconsidered so that the infants' milk depôt might be allotted its proper place in our collective organisation for the protection of the public health.

The infants' milk depôt is a feature of the new preventive medicine, which is concerned not only with the hygiene of the environment but also with the hygiene of the person, and its object is to prevent the heavy infantile mortality due to defective infant feeding. Defective feeding is, of course, not the only cause of infantile mortality; there are many other conditions which have not yet received the attention their importance demands—such, for instance, as the conditions affecting the unborn child during the period of gestation. Still, we may regard defective feeding as the chief cause of infantile mortality and it is certainly the cause which has of late years received the most attention from sanitary authorities. In most towns a municipal leaflet on infant feeding forms part of the circulating literature of the district, and usually the directions in such advisory leaflets are supplemented by the oral instruction of health visitors. The infants' milk depôt should not, then, be regarded as marking a new departure in our methods of public hygiene. It is rather an extension of the system of municipal direction of infant feeding which was at work years before the first milk depôt opened its doors in the last year but one of the nineteenth century. Nor should the work of a milk depôt be looked upon as limited to the handing of bottled, modified, and more or less sterilised milk over a municipal counter. The main function of the infants' milk depôt is to serve as the nucleus of an organisation for the feeding of infants under municipal direction and supervision. This is the point I wish to emphasise in the following remarks.

The infantile mortality dependent upon defective infant feeding is, broadly speaking, a mortality of hand-fed infants.—If all babies could be secured an adequate supply of mothers' milk during the first 12 months or the first nine months, or even the first six months, of life our mortality tables would present a very different appearance. Fortunately there is reason to think that in most towns at all events breast-fed babies are still in a majority. Hand-fed infants form, as Dr. J. F. J Sykes has pointed out, a residuum; but the important point to remember is that it is this residuum that afflicts us with the enormous mortality from diarrhœa and malnutrition against which our preventive methods are chiefly directed. There are two ways of dealing with this residuum of hand-fed infants. One is to promote breast-feeding, so as to reduce the residuum to the smallest possible dimensions; the other is to improve the artificial food supplied to the hand-fed infants, so that their hand-feeding may do them as little harm as possible. Broadly speaking, it may be said that while the encouragement of breast-feeding is the chief feature of the French methods of preventing infantile mortality, we in this country have devoted ourselves mainly to the improvement of artificial feeding. The infants' milk depôt may be made a means to promote both these objects if it be conducted somewhat on the following lines.

In the first place, it is important that the milk should never be supplied in such a way as to run the risk of discouraging breast-feeding. Care should be taken to admit to the depôt only those infants for whom satisfactory breast-feeding is impossible to secure During the last year I was connected with the Battersea depôt the milk was not supplied for an infant under nine months unless the mother could satisfy me, by the production of a written recommendation from a medical man or otherwise, that she was unable to suckle her child. In this way I was able to persuade a number of mothers, who would otherwise have prematurely weaned their babies, to continue to suckle. In some cases, where it was impossible for the child to be wholly breast-fed, partial breast-feeding was secured, the mother's milk being supplemented by a supply of cows' milk from the depôt. In all cases, however, the applicants were repeatedly assured that the depôt milk, like all artificial foods, was but a poor substitute for mother's milk. I would urge the importance of taking precautions of this kind. If the milk is supplied to all applicants without discrimination we lay ourselves open to the charge that we discourage breast-feeding and are therefore guilty of *lèse maternité.*

Secondly, the infants should be under periodical medical supervision. In the French institution, the goutte de lait, from which our milk depôts are derived, the chief feature of the work is not by any means the distribution of the milk but the systematic weighing and medical supervision of the infants. Every week the baby is brought to the depôt, where it is weighed and examined by the medical director of the institution. Most of the British milk depô direct medical supervision, but a certain amount supervision is secured by the domiciliary visitation by lady inspectors and health visitors, acting under the instructions of the medical officer of health. This domiciliary visitation is very valuable work. The mother can be influenced and instructed with more effect in her own home than anywhere else. In the work of the Glasgow depôt, however, the advantages of both methods are combined. Within the last few months the corporation of Glasgow has appointed a lady doctor to visit the homes of the infants fed from the municipal milk depôt and to weigh the babies and to supervise their progress generally. This appointment is a valuable and significant development of the work of the infants' milk depôt. It marks a new departure in preventive medicine by bringing medical women into the practical work of public health administration. Public health work is work for which women doctors are especially well fitted, and it is to be hoped that the number of medical women employed in such work will be much increased in the future. I should say, however, that Glasgow is not the first town to enlist the services of medical women in the prevention of infantile mortality; that honour belongs, I believe, to Huddersfield. There is no reason, however, why the advantages of this systematic medical supervision (including weighing) need be restricted to the babies fed on the depôt milk. Nursing mothers should also be encouraged to bring their babies to the depôt to be weighed and supervised. In this way it would be possible to secure a continuance of breast-feeding for many infants who are now prematurely weaned. Many women give up suckling, and deliver up their babies to the bottle on the advice of ignorant friends or relatives because their milk appears to disagree with the baby. In such cases what is wanted is not the premature weaning which now too often occurs, but a skilled regulation of the mother's diet and mode of life so as to make the milk more suited to the baby's needs. This could be insured by a system of municipal supervision of sucklings. I see many possibilities in the system of municipal supervision of infant-feeding which has been developed by the milk depôts. We have heard a good deal lately about the medical inspection of school children but the medical inspection of infants is equally important and necessary. At the present time many mothers do not seek medical advice on child-rearing until the child is already ill, often so ill as to be beyond the hope of recovery. It would be far better that such advice should be given to her while the child is still healthy. I have no doubt that the medical supervision of infant-feeding by municipal medical men for the purpose not of curing but of preventing disease, will become an important feature in our system of State medicine. We are awaking to the realisation that every baby born to us is a national asset, and sound national policy no less than humanitarian feeling dictates that no effort should be spared to secure the physical efficiency of those to whom will be committed the future of our country.

---

[1] A paper read before the National Conference on Infantile Mortality.

There is another way in which the practice of the British milk depôts might be improved. In all our depôts, so far as I am aware, the milk is either sterilised or pasteurised; and without entering upon a discussion as to disadvantages of sterilised milk, which I think have been greatly exaggerated, we must all admit that it would be better to supply the milk pure and uncooked if it could be done. All methods of milk purification having for their object the neutralisation of existing pollution, such methods as sterilisation, pasteurisation, centrifugalisation, or filtration, we must regard as makeshifts, to be abandoned when better methods of milk production become practicable. Is it possible by strict veterinary supervision, combined with aseptic methods of milk production, the employment of bottles, and the free use of cold storage, to supply raw cows' milk to infants with impunity? The experience of the Municipal Infants Milk Depôt at Rochester, U.S.A., where such methods have been in operation for the past seven years, shows that it is quite possible to do this provided that the complete control of the processes of production, from the care of the cows onwards, is in the hands of the responsible officers of the municipality. The municipal cow is a necessary complement of the municipal milk depôt. If the methods of clean milk production which have been employed with such success at Rochester were adopted in the British depôts not only would the quality of the milk supplied be greatly improved but an object-lesson of great value could be given to the dairy farmer. An ounce of example is worth a ton of precept. One model municipal dairy farm managed on scientific methods would do more to promote the production of pure milk than any number of reports and papers on the question of the milk-supply.

In conclusion, I would again urge that the infants' milk depôt is very much more than a municipal milk-shop—a place where municipal milk is handed out to anyone who chooses to ask for it. It is, or at all events it should be, (1) an important educational influence, a school of infant feeding, the centre of a system of municipal supervision of infant feeding; (2) the source of a pure milk-supply; and (3) an object-lesson in the production of pure milk. It is by the attainment of these objects that the infants' milk depôt will achieve its justification, its permanent place in our system of preventive medicine, and its ultimate success.

Hampstead.

INFANTILE MORTALITY AND THE EMPLOYMENT OF MARRIED WOMEN IN FACTORY LABOUR BEFORE AND AFTER CONFINEMENT.[1]

BY GEORGE REID, M.D. ABERD., D.P.H.,
MEDICAL OFFICER OF HEALTH OF STAFFORDSHIRE.

THERE is no need to emphasise the importance of that phase of the infantile mortality question the discussion on which I have the honour to introduce; neither, before an audience such as this, is it necessary to occupy much time in proving what must be patent to all who have studied the question. Endless proof is available of the injury to infant life arising from the unrestricted practice of mothers engaging in factory labour, but, as it happens that I have had somewhat exceptional opportunities of gauging the effect of this practice in a large manufacturing county, a short account of certain special inquiries I have made regarding the question may be of some interest.

The artisan population of Staffordshire is grouped together in two large centres in the extreme north and south of the county, the intervening area being rural in character. From the point of view of health conditions the two grouped populations, north and south, may be said to be identical and in both cases the general influences which operate in causing a high infantile mortality prevail largely and to an equal extent. In one respect, however, there is a marked difference in the two populations arising from the special industries carried on in the two centres, the workers in the north being mostly potters while those in the south are miners and iron workers; therefore in the north a very large number of women, both married and single, are engaged in factory labour, whereas in the south the trades carried on afford practically no employment for women.

Some 16 years ago, when my public health work in Staffordshire began, I was very much struck with the great excess in the infantile mortality-rates of the northern artisan towns compared with those of the southern towns, high though the latter were; and this led me to make special inquiry into the question, with the result that the dissimilarity could not be accounted for by any apparent difference in the general sanitary surroundings of the two populations. The conclusion then presented itself that in the married woman labour question the key to the situation might be found. With the view of more stringently testing the accuracy of this hypothesis the towns, irrespective of geographical position in the county, were as far as possible specially classified into three groups according to the proportion of married women workers in each, with the result that the infant mortality-rates were found to vary in direct proportion to the number of such workers. From year to year since then these figures have similarly been classified, and the results have unfailingly, and in a very marked manner, supported the conclusion originally arrived at. Whether, from the operation of other causes, the general infantile mortality happened to be high or low from year to year, practically the same proportionate increase or decrease, as the case may be, in the three groups of towns was maintained.

In classifying the towns into groups in the first instance I obtained the necessary information as to the relative number of married women workers from district medical officers of health and manufacturers, but, while all care was taken to insure accuracy, in the absence of any available figures the classification was merely approximately correct. In 1902, however, the Registrar-General was good enough to supply me with certain figures, specially extracted from the 1901 census returns, showing the number of married and widowed females engaged in specified occupations in each of the towns in question, together with the number of females living at various ages. From these figures I estimated, in the case of each artisan town, the percentage of married and widowed females engaged in work involving absence from home during the day per total females between the ages of 18 to 50 years, but I had no data to allow of the number of married as distinct from widowed females being arrived at. Also, in order to make use of the Staffordshire infantile mortality returns which were available for 24 years I was obliged to assume that the number of married and widowed out-workers to the female population within the specified age limit was the same throughout the whole period as in the last census year, an assumption which, I think, is justified by the fact that no change has taken place in the special trades carried on in the various towns during that period.

---

[1] A paper read before the National Conference on Infantile Mortality.

On the new basis I have reclassified the towns (artisan only) into three groups, placing in the first group those in which the proportion of married and widowed females engaged in work away from home to total females between 18 and 50 reached, and exceeded, 12 per cent., in the second group those towns in which the proportion was under 12 per cent. and over 6 per cent., and in the third group those in which the proportion was under 6 per cent.

In the following table the rates in the different groups of towns are given.

Class according to percentage of married and widowed workers to female population between the ages of 18 and 50 years.	Number of towns.	Total population, 1901 census.	Deaths of infants under one year per 1000 registered births.		
			1881 to 1890.	1891 to 1900.	1901 to 1904.
I.—12 per cent. and over	5	132,299	195	212	193
II.—Under 12 per cent. and over 6 per cent.	13	263,868	165	175	156
III.—Under 6 per cent.	8	131,508	156	168	149

As a matter of fact, the more accurate method of classifying the towns as compared with the classification previously adopted has not caused any appreciable alteration in the relative mortality in the three groups, and I submit that the figures bear out my contention that, in the absence of any other apparent reason, the excessive mortality in the first group compared with the second and third, and in the second compared with the third is attributable to the nature of the trades carried on as affecting the facilities for the employment of women away from home, and as a consequence the proportion of wholly artificially fed to entirely or partially breast-fed infants.

There is another aspect of the question, however, apart from that which more directly results from mothers neglecting their home duties after their children are born, and that is the effect, as regards the viability of the unborn, of mothers engaging in other than domestic work up to the time of their confinements. While all must realise how undesirable this practice is, the extent of the injury directly attributable to it cannot very readily be demonstrated by figures. In time, however, I think we shall have data available in connexion with the administration of the Midwives Act which may throw some light on the question. This Act has only been in practical operation for a little over 12 months and it has taken some time to get the machinery into efficient working order; nevertheless, through the energy of two inspectors working under the Act in Staffordshire I am able, even at this early date, to submit certain figures which, having regard to the difference between the north and the south, in the matter of women employment, are very significant. Under the rules of the Central Midwives' Board certificated midwives attending abnormal cases have to call in medical assistance and notify the fact to the local supervising authority and they have also to notify all stillbirths occurring in their practice. This being the case, allowing that working in a factory up to the date of her confinement is detrimental to the mother, one would expect, other things being equal, that the abnormalities and the stillbirths in the pottery towns would exceed those in other artisan towns where the nature of the work does not afford employment for women. For the purpose of inspection under the Act the county is divided into northern and southern areas, the former comprising the populous pottery towns and the latter the equally populous towns inhabited by miners and iron workers. Up to the present time the following are the relative figures for the two areas as regards notifications received of (*a*) abnormalities and (*b*) stillbirths in the practice of registered midwives per 1000 births registered:—

	Abnormalities.	Stillbirths.
North	15·0	9·4
South	6·0	3·2

The figures appear small in both cases, but it must be remembered that the rates are calculated upon the total births, whereas only a proportion of these were attended by registered midwives, many having been attended by medical men, or by unregistered midwives, who are not yet entirely barred from work. It is also important to note that, although the records cover a period of 12 months, the number of notifications sent in was much smaller than it should have been owing to ignorance on the part of the midwives in the first instance regarding the rules to be observed. Again, included in the areas covered by the returns in this case are the rural districts and one or two small non artisan towns. All these disturbing circumstances, however, are equally operative in both areas, and the figures, so far as they represent the position, may be said to be comparable. When the Act has been longer in operation and the midwives become better informed regarding the rules the number of notifications sent in will no doubt greatly increase and I also hope in time to obtain further and more exact data for comparison.

So much for the effect of the practice of married women working in factories upon the infantile mortality. I would point out, however, that the damage done cannot entirely be measured by mortality figures, for these take no account of the impaired vitality of the infants who manage to survive to swell the ranks of the degenerate.

If, then, the injury is as great as we believe it to be—and this can hardly be disputed having regard to the evidence adduced in endless official reports as well as the findings of special commissions—one is inclined to ask, Why should it still be necessary to agitate for the adoption of remedial measures? Surely public opinion is now sufficiently ripe for legislative interference, especially in view of the fact that the State already concerns itself regarding the conditions of employment in trades which are detrimental to the health of the workers. But if humanitarian arguments alone do not afford sufficient incentive for action will not the less unselfish desire to counteract the effect of the diminishing birth-rate serve as a more potent argument having regard to national prosperity? But, convinced though we may be of the need for State interference, to make a practical suggestion regarding the form it shall take is for many reasons by no means easy. Clearly the efficient remedy would be to prevent married women from working in factories or away from home unless they are in a position to show that necessity compels them to do so. Such a claim would with reason frequently be advanced, but I am confident that in the majority of cases there is no real need for married women at the child-bearing age to engage in work away from home, and, if this be so, enforced restraint would merely result in a smaller sum per week being available for the husbands' indulgence, a result which in itself is much to be desired. In this, as in most matters, however, we shall probably have to be satisfied in the first instance with less than we know to be desirable. The restriction now imposed by law of one month's abstention from work after her confinement is advantageous to the mother but it does not materially benefit the child. If, however, the restriction extended to three months the probability is that the mother would suckle her child during that time and thus the most precarious period of the infant's life would be tided over and the chances of subsequent survival would be considerably enhanced. How to prevent mothers from working previously to their confinement is a more difficult matter and to attempt to enforce any specific restrictions would, for obvious reasons, be found to be impracticable. On the other hand, there is no reason why the need should not be recognised and provided for, it being left to the factory medical officer to determine the time in each case when pregnant women shall give up work.

Stafford.

THE INCREASE OF THE POWER OF LOCAL AUTHORITIES WITH REGARD TO MILK-SUPPLY.[1]

BY A. K. CHALMERS, M.D. GLASG., D.P.H. CAMB.,
MEDICAL OFFICER OF HEALTH OF THE CITY OF GLASGOW.

THE object of this discussion is to consider what alteration in existing legislation seems to be necessary to enable local authorities to insure the provision of a pure milk-supply. At present milk-supplies are controlled by the Dairies, Cowsheds, and Milk Shops Order and by certain clauses in the Public Health and Sale of Food and Drugs Acts. These are of general application but the last named, as applied, has usually reference to variation in the normal constituents of milk present in a particular sample, while the clauses of the Public Health Acts aim at preventing the sale of milk which has, or is likely to, become infected. In addition several larger towns in England possess further powers on the lines of the Manchester milk clauses. These deal with specifically infected milk and their object is therefore akin to that of the clauses of the Public Health Act. They refer to tuberculosis of the udder; and in Scotland there are the somewhat parallel provisions in certain adoptive clauses of the Burgh Police Act, 1903. It is therefore solely through the provisions of the Dairies Order that local authorities are enabled to deal with the sanitary condition of milk premises and to take such steps as seem likely to prevent the infection or contamination of milk.

It is unnecessary here to consider in any detail how the above purposes are to be accomplished. It is sufficient to note that in general their aim is to secure the health of the stalled animals and cleanliness in the production and distribution of milk. Certain structural and sanitary requirements must be observed and a prohibition is placed on the handling of milk by persons suffering from infectious disease. Contamination, so far as it is likely to arise from structural defect in the premises, is to be prevented; and the milk of animals suffering from certain diseases is to be withheld from sale. Chiefly, however, the Order placés in the hands of local authorities power to frame regulations for controlling the conditions under which milk is produced and sold within their several districts. Everything therefore which tends towards stringency in the form, or efficiency in the application, of these regulations depends on the view taken by a local authority of its responsibility. Some make considerable effort, others are satisfied with a less exacting standard; in others the power to regulate has been left in abeyance.

Through the courtesy of the Local Government Board for Scotland I am able to introduce here a statement of the number of local authorities who have there availed themselves of this power:—

Information as to the Number of Local Authorities that have adopted Dairy Regulations in Scotland.

Local authorities.	Landward.	Burghal.	Total.
Number of local authorities in Scotland	107	205	312
Number of local authorities that had regulations in force *prior* to the coming into operation of the Dairies Order, 1899	79*	87†	166§
Number of local authorities that have adopted regulations *subsequently* to the coming into operation of the 1899 Order	3	52	55
Total number of local authorities that have dairy regulations presently in force	82	139	221

* Of these seven revised their regulations after the coming into operation of the Order of 1899.

† Of these 14 revised their regulations after the coming into operation of the Order of 1899.

§ Of these 21 revised their regulations after the coming into operation of the Order of 1899.

Mr. Power, principal medical officer of the English Local Government Board, has informed me that of 1134 urban district councils in England and Wales 804 (approximately) have adopted the regulations, while of 657 rural district councils about 364 have done so.

Limited scope of present regulations.—A moment's reflection on the history of dairy legislation will make it clear why, despite all our provisions, there should still be a demand for increased power of control. In point of time the conception that disease might be spread by water anticipated by a few years the parallel conception that it might also be spread by milk. And as the diseases which afforded the earlier illustrations in both cases were of the major epidemic sort our dairy legislation was devised against disease in the concrete and on the assumption that the evidence of its presence was written in characters which could not be mistaken. So that when the Dairies Order prohibited anyone sick of an infectious disease from handling milk it had in view the dairyman's family and the more obvious risks arising from the storing of milk in vessels kept in a living apartment; the cleansing of milk vessels in a polluted water-supply, or the alternate use of the milk scullery as a domestic washing-house. And as with diseases of the dairyman, so it was with diseases of the dairy stock. Cattle plague, pleuro-pneumonia, and foot-and-mouth disease represented until quite lately the only diseases of cattle which debarred their milk from sale for human food, and although tuberculosis of the udder has now been added, we do violence to our knowledge of the laws both of physiology and of disease by assuming that any form of acute febrile disease in a milk animal other than these named is without pathological significance or can fail to influence the character of the milk yield while the disease continues.[2] For example, septic and acute gastro-intestinal affections in animals, non-tuberculous affections of the udder, teat eruptions, &c., have still no place in dairy legislation, although all of them have at one time or another been demonstrably associated with disease in the milk consumer.

All this notwithstanding, it is not my intention to suggest that dairy legislation has failed to accomplish considerable reform where local authorities have been disposed to make use of their powers. But during the years since the Order was framed the whole pathology of dirt has acquired a new significance and its bearing on the causation of disease has rapidly outstripped our legal phraseology. Justice, indeed, requires us to admit that local authorities have as a rule failed to make useful application of this knowledge; and it is to some of the larger milk companies in this country and abroad that we must go for illustration of successful application, to the technique of the dairy, of the teachings of the research laboratory. For while administrative effort has almost too exclusively confined itself to producing reform in the structural environment of the milk-supply and only in the actual presence of disease has concerned itself to any great extent with the habits of the milker, commercial companies have shown us that the hygienics of the milk question depend quite as much on intelligent handling of the milk at, and after, production. It is the application of the surgeon's conception of cleanliness to the conditions of the milk traffic which these companies have taught local authorities; it is the adoption of measures to prevent contamination in a sense very different from that which obtained when the Dairies Order was framed which is so desirable—so necessary in fact; and it is this which I venture to suggest is impossible of attainment through the operation of any regulations which the present Dairies Order enables us to make. By these channels we have reached the conception of a pure milk-supply, free not only from the germs of specific disease obtained from the animal or its attendant but also from those other elements of contamination which lurk in the dust of byres and in every milking pail, milk churn, and dish through which the milk passes on its way to the consumer. I do not forget that it has been argued that the greater contamination of milk only occurs *after* it has reached the household of the consumer, but as evidence that the purveyor does not accept this as a satisfactory explanation of all the impurity we have only to remember the widespread use of chemical preservatives and the rapid growth in recent years of the practice of commercial pasteurisation. Both have one aim, and both, moreover, by implication range the purveyor among those who affirm that milk requiring either has been produced under conditions which are not satisfactory.

---

[1] A paper read before the National Conference on Infantile Mortality.

The need for extension of the Dairies Order.—It is pertinent to ask why local authorities have failed to bring administrative requirements into line with this advancing knowledge of the sources of milk contamination. Of recent years the question of tubercle in dairy herds has almost excluded from view other important phases of dairy legislation. It explains also, I think, the inaction which we are here considering, for the Dairies Order is defective and the local authorities are inactive, not because of unwillingness, but from inability to accomplish what is so necessary. In particular the Order is too restricted in its definition of disease as affecting animals and fails probably most of all in the optional character of the provision contained in its Article 13 enabling local authorities to regulate the conditions of the milk traffic. Moreover, the scope of the regulations is limited and does not include the food or toilette of the animal or provide for the withdrawal from sale for food of milk obtained from animals undergoing treatment by drugs which are known to affect prejudicially the character of the milk. I suggest to you, therefore, that in any new Dairies Order disease in animals should, for the purposes of the present Article 15, include every general disease accompanied by fever, all acute affections of the gastro-intestinal tract, and inflammatory affections of the udder and teats.

Regarding teat eruptions there is, I think, evidence to suggest that even a superficial sore may add to the milk not only the morbid products common to all diseased surfaces but may afford a suitable culture field for bacillary growths with pathogenic properties; and I have before me notes of a recent series of sore throats presenting all the clinical features of diphtheria and occurring contemporaneously with the presence of such sores as I have indicated, from which an organism was recovered by culture which failed only in the final test of virulence to animals.

Notification by the cowkeeper of disease among his herd has its advocates, but the almost universal neglect of the parallel obligation imposed on the householder under the Infectious Disease (Notification) Act does not suggest that notification by the cowkeeper would be better observed. The more hopeful method would seem to be frequency of inspection followed by a penalty on conviction of any contravention of the regulations and the destruction of the animal when suffering from any infectious disease likely to affect its milk permanently. But it may be asked whether regulations of the character we are now considering are likely to insure a milk-supply which will reach the consumer in a fresh and wholesome state.

The technique of the modern dairy includes filtering and cooling, sometimes bottling and sterilising, and it is suggested that milk treated efficiently by either method can only be supplied at a prohibitive price. This can be true only so long as a fractional portion of the supply is so treated. Extend the demand for it and by coöperation the economic difficulties of the milk producers on a small scale will disappear. And the way to extend the demand is by the creation of an educated public opinion which this Conference will, we hope, do something to further. But more would seem to be necessary. Administratively the principle of empowering one local authority to interpose between another local authority and its responsibilities is, I think, objectionable and only excusable on the plea of hopeless remissness. There can be no doubt, moreover, that the consumer of the milk is the more likely to have his critical faculty highly developed and hence regulations and customs deemed satisfactory by a rural authority may quite reasonably fail to gain acceptance in a neighbouring town. If, then, the larger neighbours are to maintain a policy of non-interference, are they to remain inactive?

Is it not the case that knowledge regarding the dust impurities in milk is steadily pointing in the direction of a bacterial standard of purity, that some organisms are inoffensive, while others are highly offensive in origin, and that in some countries summary destruction follows the discovery of any milk found on sale at a temperature exceeding a given maximum? I suggest to you that regulations of this character would form a most efficient stimulus to reform in dairy methods. On such lines we must, I think, ultimately reach the provision of a pure milk-supply, but meanwhile voluntary action on the part of local authorities would accomplish much.

We have before us illustration of the success which has attended a system of certifying milk produced and distributed under rigidly hygienic conditions, and were the local authorities of the large towns in this country to agree upon voluntary registration of such dairies as observed similar precautions, and to issue certificates which would form a guarantee of the character of the milk we should have begun to level up the standard of our milk-supplies.

I have said nothing regarding the difficulty which certain corporations have experienced in financing infants' milk depôts. In Scotland this difficulty has not been felt, and although the Milk Depôts (London) Bill of last year, which would have legalised the establishment of milk depôts by the metropolitan boroughs, was dropped, the principle has, I believe, been embodied in the Borough of Woolwich Act of this year.

The sediment in milk.—As illustration of the impurity, which it should be the object of regulations to prevent, I submit a statement prepared by Dr. R. M. Buchanan, bacteriologist to the corporation of Glasgow, of the microscopic and bacterial characteristics of some sediment which I caused to be obtained from milk produced on farms where considerable effort is made to conform with existing regulations. This fact explains, I think, the relative smallness of the volume of sediment recovered, although it scarcely affects its character. It is our practice in Glasgow to pass all the milk supplied to the Infant Milk Depôt through an electrically driven separator and the sediment of 150 gallons was examined on several successive days. Dr. Buchanan's description is as follows:—

The five deposits submitted consist of repulsive pultaceous masses, composed of greyish dung like material, interspersed with hairs, and covered with dirty greyish slime. Two of the samples selected for detailed examination presented the following appearances

Microscopical examination.—(*a*) Greyish dung like material showed many dust-like particles of an indefinite nature black, yellow, and brown; fragments of vegetable fibres—a few colourless but majority yellowish brown and some apparently partly digested; some semi crystalline translucent masses varying in size; squamous epithelial cells in large number; leucocytes a few; fat globules a few; and hairs a few. (*b*) *Dirty greyish slime.*—Consisted mainly of leucocytes; numerous fat globules and fatty particles; squamous epithelial cells were abundant but scarcely any dust particles or vegetable fibres were detected. Bacteria numerous as compared with the number in the greyish material and comprised cocci, short bacilli, and a few streptococci.

Bacteriological Examination.

—	Deposit of May 29th, 1906.	Deposit of May 31st, 1906.
Bacterial content	Estimated at 145,080,000 per gramme.	Estimated at 142.200,000 per gramme.
Bacillus enteritidis sporogenes.	Absent in 1 milligramme	Absent in 1 milligramme.
Bacillus coli.	Absent in 1 milligramme	Absent in 1 milligramme.
Coliform bacilli (bacillus lactis aerogenes type).	Estimated at 2,620,000 per gramme.	Estimated at 420,000 per gramme.

This sediment on being weighed by Mr. Harris, corporation chemist, was found to average 135 grammes, or 4·76 ounces when moist, whilst on drying at 100° C. it was reduced to 3 01 ounces. This represents over the total volume of milk an average of 8 8 grains of dried material per gallon, or rather more than one and a half grains per pint.

Glasgow.

THE STERILISATION OF TUBERCULOUS SPUTUM AND ARTICLES INFECTED BY THE TUBERCLE BACILLUS.

BY THOMAS KIRKLAND, M.INST C.E ,
CONSULTING ENGINEER TO GUY'S AND BROMPTON HOSPITALS,

AND

MARCUS S. PATERSON, M.B., B S DURH., M.R.C.S. ENG.,
MEDICAL SUPERINTENDENT OF THE BROMPTON HOSPITAL SANATORIUM AND LATE RESIDENT MEDICAL OFFICER AT THE HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, BROMPTON, LONDON, S W.

UNTIL the year 1905 it was the custom at Brompton Hospital to destroy all sputum in a cremator. The cups in which the sputum was collected were washed by hand and sterilised. The patients were supplied daily with new handkerchiefs which after use were burnt. These methods seemed undesirable to the medical staff for the following reasons: (1) the risk of infection to those employed in sterilising, &c. (2) the considerable expense entailed in keeping the cremator in repair; and (3) the cost of special handkerchiefs. We were therefore asked to devise a scheme by which these objections might be overcome.

Turning our attention first to the question of the sterilisation of the sputum we decided that it would be advisable, if possible, to abolish the cremator and to substitute a receptacle in which the sputum would be sterilised by the action of steam at a temperature of 250° F. Before this method could be advised it was necessary to determine what the action of the steam on the sputum would be, as if it had the effect of coagulating the sputum the portions thus coagulated might escape sterilisation, and further, such unsterilised coagulated particles of sputum might adhere to the sides of the apparatus and thus become a source of infection. In order to test the matter we experimented on sputum placed in a small iron vessel under the pressure necessary to keep the steam at the required temperature and found that the sputum, so far from coagulating, tended to become more liquid the higher the temperature, and, moreover, did not adhere to the sides of the apparatus The sputum so treated was afterwards injected into guinea pigs and as the result of three independent observations it was found that the guinea-pigs so inoculated were not infected with tuberculosis, whereas control animals injected with unsterilised sputum in all cases developed the disease.

Upon the evidence of these experiments the committee of management decided to have two steam sterilisers constructed of the capacity of 20 gallons and they have now been in use for 14 months.

The sputum treated in these sterilisers has been tested by Mr. L. S. Dudgeon with the following results:

I.—*Control animals.*—Two guinea pigs were injected. They were killed at the end of seven days Post mortem they showed tuberculous abscesses at the seats of inoculation and local glands. Tubercle bacilli were present in the pus and in the glands. Two guinea-pigs were injected and were killed at the end of 14 days. Result: There was general tuberculosis of the viscera below the diaphragm and of all the glands on the injected side. Tubercle bacilli were present in the glands. In each of the following two guinea-pigs were injected.

II.—Sputum raised to 250° F. Result: No tuberculosis at the end of five weeks.

III.—Sputum raised to 212° F. for 20 minutes. Result similar to II.

IV.—Sputum raised to boiling point for ten minutes. Result similar to II.

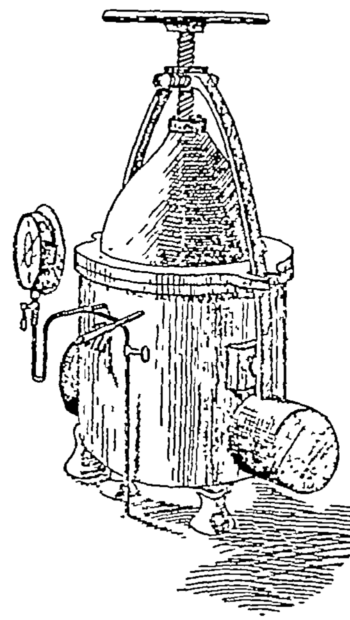
V.—Sputum raised to boiling point for five minutes. Result similar to II.

VI.—Sputum raised to 200° F. Result similar to II.

Therefore in no case did any of the guinea-pigs other than the controls develop tuberculous foci.

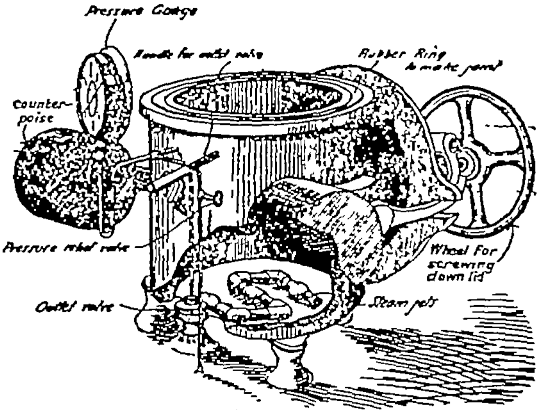
Each steriliser consists of an iron vessel with a moveable lid (Figs. 1 and 2), having at the bottom two steam jets so arranged that a circular motion is given to the contents. The sputum having been poured into the vessel the lid is screwed down and steam is allowed to enter until a pressure of 15 pounds (corresponding to a temperature of 250° F.) has been obtained. The contained sputum is allowed to boil under the action of steam for a period of 20 minutes, after which it is allowed to cool to a temperature somewhat above 100° F. and is emptied into the drain by opening a valve in the bottom of the steriliser, arranged so that all the contents can drain away.

FIG. 1.



Sputum steriliser with cover on.

FIG. 2.



Sputum steriliser with cover off.

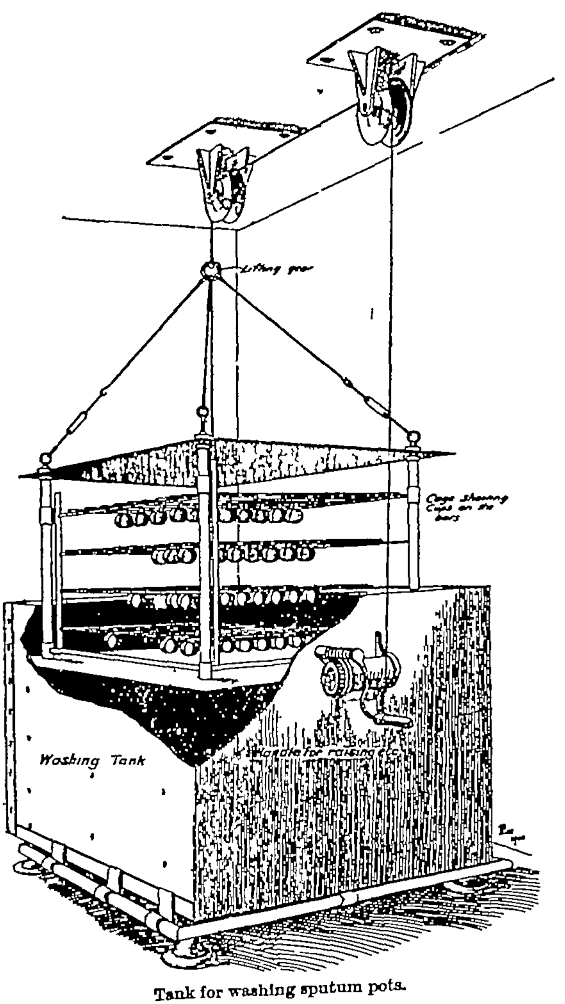
Method of cleansing the sputum pots.—The sputum pots, as has been stated, were formerly cleansed by hand. Each pot was separately washed by the man appointed for this duty, who for the sake of cleanliness and the avoidance of infection was provided with an apron, gloves, and boots of indiarubber which after use were sterilised. This procedure not only took considerable time but subjected those employed to the risk of infection if they were at all careless. Upon our suggestion and as a means of overcoming these objections the following method of sterilising sputum pots was proposed and adopted.

A large iron tank (Fig. 3) was constructed, having the necessary valves for admitting water and steam and a valve in the bottom of the tank through which the contents could be emptied into the drain. Inside the tank is a cage which can be raised out of, or lowered into, the tank at will. This cage is constructed of brass tubes framed and braced together. On the horizontal tubes the sputum cups are suspended by their handles and the covers of the cups are placed in suitable trays provided in the cage. For the purposes of sterilisation and cleaning, the cage full of soiled sputum cups and covers is lowered into the tank. Water is admitted into the tank and boiled by the admission of steam. After boiling for 20 minutes this water is emptied and the process is repeated. The cage is then raised and the cups and covers are removed. By this method much less handling of the cups is required and the cleaning of both cups and covers is found to be more thoroughly performed than when washed by hand. The saving of time effected by this method of washing the cups enables the same staff as was formerly employed in collecting and washing the cups to wash the handkerchiefs in addition.

The disposal of handkerchiefs—The old method of disposing of soiled handkerchiefs by burning them after being once used was naturally a costly and wasteful one and we therefore had to consider whether it would be practicable to sterilise them and thus render them fit for further use. It was urged that if handkerchiefs were submitted to any such method of sterilisation as has been detailed above they would be so stained and otherwise injured in the process that the extra amount of use which might be expected of them would hardly warrant the expense of the apparatus required. By the use of the test apparatus, which we have already alluded to, it was proved that handkerchiefs could be so sterilised 12 times and afterwards washed by hand without suffering any material damage. The committee therefore sanctioned the construction of the following plant for sterilising and washing handkerchiefs: (1) a combined steriliser and washing machine; (2) a hydro extractor; and (3) a calender.

The following is the procedure at present in use. The soiled handkerchiefs are conveyed from the wards in covered pails and are at once placed in the sterilising and washing machine where they are first sterilised and afterwards washed. After washing they are taken out and placed in the hydro, which, with the calender, is in a separate room. After being dried in the hydro they are passed through the calender and are then folded and returned to the wards. It has been found that handkerchiefs costing 11*d.* per dozen may be submitted to this method of sterilisation and washing about 50 times and will last for about four months. It is probable that a somewhat better quality of handkerchief would stand longer and so might prove rather more economical. At the Frimley Sanatorium, where there is a laundry with washing machines, but not a special combined steriliser and washing machine, both sputum and handkerchiefs are sterilised in the sputum steriliser. While the attendant is engaged in sterilising the sputum flasks and pots the handkerchiefs are allowed to soak in cold water to which soap and soda have been added. As soon as the sputum is disposed of the handkerchiefs along with the liquor are sterilised in their turn, a temperature of 250° F. being used, and after sterilising are dried. At the end of a week about 700 handkerchiefs have been sterilised and these are then removed to the laundry and washed in the ordinary way

FIG. 3.



Tank for washing sputum pots.

The drains from all the machines above alluded to are suitably trapped and ventilated. A sputum steriliser exactly similar to the pattern already described has been erected at the King Edward VII Sanatorium

Our experiments upon the sterilisation of sputum seem to have established a fact which has, up to the present, as far as we are aware, not been credited—namely, that articles infected with the tubercle bacillus may be rendered sterile at a temperature of 200° F. From this it follows that any articles infected with the tubercle bacillus may with certainty be rendered sterile by boiling them in water for half an hour under atmospheric pressure.

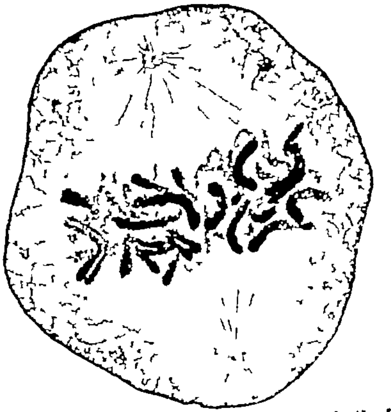
In conclusion, we desire to express our thanks to Dr H. Batty Shaw and Dr. E J. Steegmann for the help they have given us in conducting the first inoculation experiments, and to Mr. Leonard S. Dudgeon for his kind assistance in the sterilisation experiments with the new sputum steriliser

OBSERVATIONS ON THE LIFE-HISTORY OF LEUCOCYTES.[1]

BY C. E WALKER,
ASSISTANT DIRECTOR OF THE CANCER RESEARCH LABORATORIES, UNIVERSITY OF LIVERPOOL.

WHEN the fertilised ovum of a multicellular animal or plant segments a definite number of rod-like bodies appear during the process of division. These bodies are known as chromosomes. At each subsequent division of the cells in the building up of the body of the organism the same number of chromosomes appears. This number is constant in the species. Thus in the cells forming any of the body tissues of man there are 32 chromosomes, of a mouse 24, and so on. This continues in the cells of animals and plants in the building up of all the tissues until the time approaches when definite sexual elements are to be produced. At this time certain cells go through a particular type of division in which the number of chromosomes is reduced to one-half of what is found in the somatic or body cells. Thus the sexual elements possess only half the somatic number of chromosomes, and consequently when fertilisation takes place, that is, when the male and female sexual cells fuse, the somatic complement of chromosomes is regained, and a new individual is created. For example, in the case of man where the normal somatic number is 32 a spermatozoon with 16 fuses with an ovum also with 16 chromosomes, the result being that the division figure observed in the first segmentation of the fertilised ovum exhibits 32 chromosomes and this number is maintained in all the subsequent divisions until the whole body is built up and until certain cells again go through the reduction process in order to produce sexual elements. This process of reduction includes two generations of cells—that is, two divisions following each other are involved before the process is complete. The whole has been called the maiotic process and the two divisions or generations of cells involved are the first maiotic (heterotype) and the second maiotic (homotype) divisions

FIG. 1.



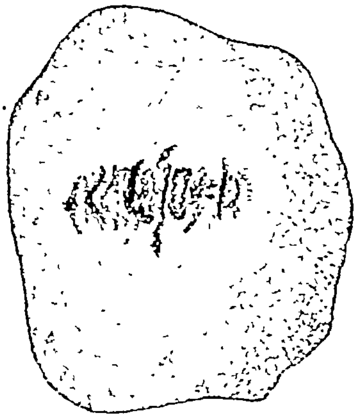
A somatic division figure The chromosomes are in the form of their rods, U s or V's

In animals the cells resulting from the second maiotic division are converted directly into sexual elements without any further division In plants, on the other hand, there may be an indefinite number of cell generations following the second maiotic division and but few of these are destined to become sexual elements. The majority form tissues with somatic characters and functions, though, having passed through the maiotic phase, they, of course, possess only half the somatic number of chromosomes. It has therefore always been assumed that herein there existed a difference between the cycle of cell generations of multicellular animals and plants, for while in animals those cells which have reduced are all converted directly into sexual elements, in plants only a few such cells may become converted into sexual cells, the rest performing the functions of supporting and nourishing the few. Moreover, in plants apparently any number of generations of cells may intervene between reduction and the production of sexual elements.

---

[1] Abstract of a paper read before the Royal Society on Jan. 18th, 1906

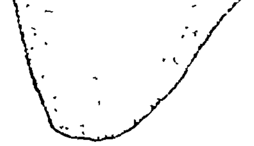
FIG. 2.



A first maiotic (heterotype) division figure. There are one-half the number of chromosomes found in the somatic division. The chromosomes are in various definite forms.

The observations recorded in a communication to the Royal Society on the Life History of Leucocytes by myself claim to show that in the generations of leucocytic cells we have phenomena which run more or less parallel with the post-maiotic (reduced) generations that exist in prothallial tissue in plants. It is first explained that the term leucocyte is intended to include all the wandering nucleated cells of the animal body. In the male sexual gland the sequence of events among those cells that are destined to be sexual elements is as follows. Up to a certain point the cells in question divide in a similar manner to the cells forming the ordinary body tissues and exhibit the full somatic number of chromosomes. This is known as the somatic type of division. The somatic are followed by amitotic divisions. That is without the appearance of any spindle figure or chromosomes —a similar division, in fact, to that of a drop of viscous fluid into two drops. After this come further somatic divisions, followed immediately by the first and second maiotic divisions. The cells resulting are converted directly into sexual elements. Among the leucocytes and their immediate ancestors a very similar series of events occurs. First we have amitosis and somatic mitoses alternating with each other just as in reproductive tissue. Then follow divisions which are similar to the first and second maiotic divisions, where the chromosomes are reduced in number to one-half of that found in the somatic cells. Here the similarity to animal reproductive cells ends and that to the reduced tissues in plants begins. Apparently there is an unlimited number of post-maiotic generations among the leucocytic cells. Furthermore, in another communication to the Royal Society[2] it is claimed that these reduced leucocyte cells may produce tissues possessing characters and functions similar to somatic tissues. If these observations are correct we have therefore a further parallel between the phenomena exhibited by animal and vegetable cells. The reduced cells of both animals and plants are out of coördination with the soma from which they have been derived. I consider that the evidence in this respect with regard to leucocytes is in favour of the correctness of my observations.

FIG. 3.



A second maiotic (homotype) division figure. The chromosomes are in the same form as in the somatic division but are found to be only one-half the somatic number. This type of division is the most common among the cells of the bone marrow.

The bearing of these observations upon what happens in malignant growths may here be mentioned. It has been recorded[3] elsewhere that one of the earliest phenomena in the occurrence of malignant tumours is the invasion of the tissue cells by leucocytes with the subsequent common division of both nuclei. This produces a race of hybrid cells, half tissue cell, half leucocyte. It has also been recorded by the same authors that the cells of malignant growths reduce in a similar manner to the cells of reproductive tissues. All the forms of cell division seen in malignant tissue are also seen in normal leucocytic tissue, and both leucocytes and malignant tissue are out of coördination with the true soma. According to the present observations, then, the hybrid cells act just as would be expected and possess the characteristics, to a certain extent, of both their ancestors.

Liverpool.

ACUTE LOBAR PNEUMONIA IN A PYGMY.

BY W. HERBERT GREGORY, M.D., C.M. EDIN.

ON the evening of Oct. 14th, 1905, I was asked by Colonel J. J. Harrison to see one of the pygmies whom he brought back from the Ituri Forest. I found the patient, Matuba by name, a male, stated to be aged 23 years, lying on a mattress.[4] His temperature was 103·2° F., his pulse was 120, and his respirations were 20. By the aid of an interpreter it was found that he complained of pain in the left infra-axillary region. Three days before the patient had suddenly stopped dancing in the middle of a performance, complaining that he was tired and that his back hurt him. He was seen by a medical man and treated for a sprained muscle. No evidence of a rigor could be obtained, but the difficulty of getting any evidence of prodromata was considerable.

On Oct. 15th the temperature was 103°, the respirations were 24, and the pulse was 118, with a dry hacking cough. There was a small amount of albumin in the urine. On examination, slight dulness with some fine crepitations and rhonchi were found over the base of the left lung. There were also rhonchi over the right base, but these disappeared in a day or two. On the 16th the dulness had increased and the inflammation finally involved the whole of the lower lobe of the left lung. He was at first treated with a mixture containing one and a half drachms of antimonial wine, two drachms of spirit of nitrous ether, three ounces of solution of acetate of ammonia and water to make up six ounces, the dose being half an ounce every four hours. This was afterwards changed to a powder containing one grain of sulphate of quinine, ten grains of citric acid, and some sugar of milk, given every four hours in half an ounce of a mixture containing two drachms of bicarbonate of potash, 36 grains of carbonate of ammonia, and half an ounce of syrup of orange dissolved in six ounces of water. The diet consisted of milk, broth, and eggs. The first named was taken badly at first, as the patient had never tasted it before, but the addition of alcohol in the form of whi ky quite overcame this difficulty. During the fourth and fifth days the patient was very ill with great cyanosis and difficulty in breathing along with troublesome cough. The pulse became intermittent and oxygen and strychnine had to be administered and alcohol given freely. The case was a severe one but followed the usual course of an acute lobar pneumonia, the crisis occurring on the sixth day, when the temperature dropped from 103·8° to 97·2° in 18 hours. There was profuse sweating during this stage. There was a rise to 102 2° the following night, but after this the patient had an uninterrupted recovery.

[4] See in THE LANCET, August 12th, 1905, a paper by Dr. G. E. Smith and Dr. A. Loos upon Matuba and his companions. Matuba's age was then estimated by various osteological data as about 18 years.

An examination of the sputum (which had the typically rusty colour at first) was made by the Clinical Research Association and a certain number of pneumococci was found. An attempt was made to examine the blood for leucocytosis, but the difficulty in obtaining a specimen was so great that the idea had to be abandoned. No herpes was seen round the lips during the case. As may be imagined, the task of nursing was no light one and great credit is due to the nurse in charge of the case for the admirable way in which she managed the patient. The patient was very good throughout, although at first he was suspicious of everything done for him.

During the convalescence, which was a good one, the patient would sit for hours playing with his bow and spear, going through all the incidents of the chase. The whole case followed the course of an acute pneumonia in a white man, but the unusual type of patient has led me to report it.

Beverley.

INTERNAL SECRETION AND THE DUCTLESS GLANDS.

BY SWALE VINCENT, M.B. LOND., D.SC. EDIN.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF MANITOBA, WINNIPEG, CANADA.

PART II.[1]

THE THYROID AND PARATHYROID GLANDS.

A. Effects of ablation and disease.—No attempt will be made to give a complete account of the history and literature of the thyroid gland. Our knowledge of the subject is not based upon so secure a foundation as a perusal of modern text-books would lead one to suppose and there can be little doubt that there has been in some directions undue haste in correlating clinical experience with the results of experimental physiology. The present state of our knowledge has been reached through different modes of investigation, some of which will now be dealt with in order. As regards the effects of removal of the organs, perhaps the most generally accepted among recent views may be briefly stated as follows. As regards vital importance, the function of the thyroid gland is subsidiary to that of the parathyroids. Removal of all the parathyroids from an animal, even if the thyroid be left intact, invariably proves fatal within a short time, and this with typical nervous symptoms described under the name of "tetany." Removal of the thyroid, on the other hand, gives rise to an entirely different train of symptoms stated to be those of "post-operative myxœdema" or of "cachexia strumipriva."[2] According to this modern conception, the divergent results obtained by the older experimenters in different classes of animals were apparent rather than real, they having failed to appreciate the anatomical differences, and having, in fact, performed a different operation in each case. This theory of the supreme importance of the parathyroids was first put forward by Gley[3] who rediscovered the (external) parathyroids[4] but was more definitely formulated and elaborated by Vassale and Generali.[5] The extreme importance to life of the parathyroids has also been affirmed by Rouxeau,[6] Moussu,[7] Welsh,[8] and Capobianco and Mazziotti.[9] The question as to the extreme importance of the parathyroids cannot yet be considered as settled. Kishi[10] found that dogs and cats often die although the parathyroids be left behind. Vincent and Jolly[11] found further that removal of all four parathyroids was not necessarily fatal. We were furthermore unable to confirm some other statements which are very commonly accepted. The general conclusions reached were as follows: "1. It cannot be truly said that either thyroids or parathyroids are essential for life, since it is frequently possible to remove either or both without causing death. 2. We find, as others have done, that fatal results when they occur are not due to injuries to surrounding structures accompanying the surgical interference but must be referred to absence of the glands in question[12] 3. No statement, universally applicable throughout the animal kingdom, can be made as to the importance of the glands in question, whose functions appear to differ very widely in different classes of animals. Rats and guinea-pigs do not seem to suffer at all as the result of extirpation.[13] Monkeys only show transient nervous symptoms.[14] Dogs and cats frequently, but by no means invariably, suffer severely and die. In foxes symptoms come on with remarkable rapidity and death is correspondingly early. 4. The diversity of results obtained in different classes of animals is not to be attributed to anatomical but to physiological differences. 5. In no animal have we been able to induce symptoms resembling myxœdema.[15] 6. In young animals, although extirpation of the thyroid causes a temporary cessation of growth, we find that this is not necessarily accompanied by symptoms of a cretinoid nature. 7. Myxœdema and cretinism must then, we think, be due to causes more complex than simple thyroid insufficiency. 8. When the thyroid is removed the parathyroids appear capable of functionally replacing it to a certain extent and their histological structure changes accordingly."

Perhaps the point of most general interest in the above results is that myxœdema was never induced, even in monkeys. This result differs from that obtained by Horsley,[16] Murray,[17] and Edmunds,[18] who state that it is possible by operation to induce myxœdema in monkeys. Our animals were kept at ordinary indoor summer temperature and they showed no symptoms which could be described as myxœdematous. In some cases it was impossible to distinguish the operated monkeys from the controls and in a photograph which was taken of an operated animal and a normal one side by side the operated animal looked the healthier of the two. One of the animals, it is true, suffered three days after the operation from slight muscular tremors but completely recovered. Some of them suffered from catarrh and one died from some laryngeal affection and it seems probable that, as in the case of other animals, removal of the thyroid gland leaves monkeys in a condition in which they are less capable of resisting disease. We do not pretend that the monkeys were quite unaffected by the operation. They were, as a rule, perhaps somewhat quieter than normal; but we do insist that the striking feature of myxœdema in man—viz., swelling of the subcutaneous tissues—was totally absent.

[12] This was the result of some few experiments in which injury to surrounding structures was done without removal of either thyroids or parathyroids. No typical symptoms were observed in these cases but there is still a possibility that if a larger number of experiments were performed and the necessary conditions were understood some of the nervous symptoms may after all not be due to absence of the glands. This possibility is suggested by the fact that tetany may come on at variable periods from five hours to a week after operation.

[13] Such extirpation including parathyroids as well as thyroids.

[14] In a new series of observations by Mr. Jolly and myself the results of which have not yet been published, one monkey died within 24 hours after the operation with what appeared to be typical tetany It was found, however, post mortem that the recurrent nerve and other structures had been included in one of the ligatures.

[15] I.e., there has been no swelling of the subcutaneous tissues.

[18] Journal of Pathology, vols. iii., v., vi., and vii., 1896-1900; the Pathology and Diseases of the Thyroid Gland, Edinburgh and London, 1901.

It is important to note that removal of the parathyroids, included of course in the complete operation, has not proved fatal and if it should ultimately be determined that simple parathyroidectomy without injury to the thyroid is a fatal operation it will show that removal of parathyroids alone is much more serious than extirpation of thyroids and parathyroids together. This has, in fact, been alleged by some observers.

Of course, it is open to insist that somewhere in the body of the above-mentioned animals there were accessory thyroids or parathyroids which sufficed to maintain life after the removal of the main organs. We can only reply that a most careful search for such bodies has always been made and that in the absence of positive evidence their existence is a pure conjecture. Moreover, if accessory glands be so usually present, then the question as to the importance to life of the glands ceases to have the value hitherto attached to it.

Another point of importance in the above research is the observation that when parathyroids alone are left behind they appear to take on both the structure and the function of the thyroids. This will be referred to again in connexion with the question as to the relation between thyroids and parathyroids.

B. Artificial renewal of thyroid and parathyroid secretion.—1. By grafting. There can be little doubt that the leaving behind of a thyroid lobe, or even, according to the majority of authors, a very small shred of thyroid tissue, will suffice to keep the animal in good health. This observation naturally led to experiments in the direction of grafting. Schiff,[19] who was the first to perform in a systematic manner extirpation of the thyroid, was also the first to attempt grafting. But his grafts *quâ* grafts were not successful.[20] He, however, states that he succeeded in prolonging the life of his dogs after thyroidectomy, but this success may have been due, according to the modern conception, to the temporary supply of thyroid secretion furnished by the gland substance and analogous to a subcutaneous or intravenous injection of thyroid extract or to a process of feeding with thyroid substance. Schiff operated upon dogs with the thyroids of other dogs, two to five weeks before performing thyroidectomy. The grafts did not "take" and were gradually absorbed. Since the time of Schiff very numerous grafting experiments have been performed.[21] These were for a long time unsuccessful.[22] It was not until Eiselsberg's second publication [23] that any really satisfactory grafting experiments were recorded. This author found that in four cats the operation was completely successful, both from an anatomical and a physiological standpoint. A little later appeared a series of papers by Cristiani,[24] who was equally successful in 16 out of 19 rats in his earlier series of experiments and who afterwards performed a very large number upon many different species of animals. Pantaleone [25] was not so successful, while Munk [26] was only partially successful. Enderlen [27] and Sultan [28] obtained fairly good positive results. Cristiani,[29] by taking special precautions, succeeded in thyroid grafting in all species of animals in which he tried it. In order that the graft should be successful it is necessary that the organ transplanted should not be too voluminous. For small animals (rats, young weasels, &c.) one can graft entire lobes of the gland, but for larger animals it is necessary to divide the organ into flat or elongated slices. The thyroid graft carried out under these conditions and with the surgical precautions detailed by Cristiani not only does not become absorbed but actually increases according to the needs of the organism into which it has been grafted. Grafting may succeed not only when performed into a different part of the body of the same animal but also between different animals of the same species and sometimes also between different species and even families.[30]

The success of these grafting experiments in preventing the onset of symptoms after thyroidectomy is a very strong argument in favour of the view that the ill-effects following the extirpation are in reality due to the loss of the internal secretion of the organ and not to injury to nerves or other similar cause. In the experiments referred to above the graft was a "thyroparathyroid" graft. Some work has, however, been done in the direction of pure parathyroid grafts and apparently with some measure of success.[31]

Horsley [32] suggested that grafting should be tried in man to arrest the progress of myxœdema. This was carried out with partial success by Bircher [33] and by Bettencourt and Serrano.[34] But as in the case of Schiff's grafting experiments the grafted gland was in most cases absorbed and the beneficial effects were not permanent. Only in one case has the improvement lasted for more than a few months. This was in a case of myxœdema recorded by MacPherson,[35] in which all the symptoms disappeared after the operation and had not returned three years later.

2. *By injection of juice or extracts of the glands.*—Pisenti and Viola [36] appear to have been the first to employ experimental opotherapy. Vassale [37] and Gley [38] found that a temporary benefit accrued after thyroidectomy if the animal were subjected to an intraperitoneal injection of thyroparathyroid juice. But these results have not been obtained by all observers [39] and according to some writers the extract to be of any service must contain *parathyroid* juice. It is, indeed, stated that pure thyroid extract is actually harmful after cases of extirpation of both organs.[40] It has further been held that injection of parathyroid extract is of great benefit in preventing or postponing the symptoms due to absence of parathyroids.[41] Murray [42] also employed a glycerine extract of sheep's thyroid with which he treated monkeys after thyroidectomy. This author found that in some cases the symptoms disappeared, but in others there was only an improvement and death afterwards ensued with acute nervous symptoms.[43] He suggests that in the latter case the parathyroids were extirpated along with the thyroid, while in the former they were left behind,[44] and he says that it is not surprising that the parathyroid symptoms are not relieved by thyroid treatment.[45]

[42] Op. cit.

[43] But monkeys frequently recover from the nervous symptoms even if no thyroid treatment be adopted.

[44] In most common species of monkeys, at any rate, the parathyroids are practically certain to be removed along with the thyroids.

[45] But it must be borne in mind that the thyroid extract would contain also parathyroid substance. He does not state, at any rate, that the parathyroids were cut away before the extract was made. The supporters of the view that the parathyroids possess a separate

3. *By administration of thyroid and parathyroid extract by the mouth.*—This method was first employed by Howitz,[46] E. L. Fox,[47] and Mackenzie,[48] and was soon universally adopted for the treatment of myxœdema. It has been found to be just as efficacious as injection intraperitoneally or subcutaneously.[49]

C. The question as to an intimate functional relationship between thyroids and parathyroids.—Some of the earlier observers looked upon the parathyroids as simply undeveloped portions of the thyroid gland. The actual transformation of parathyroid into thyroid tissue has been denied by the majority of investigators.[50] Gley, who was the chief supporter of the theory that the parathyroids were embryonic thyroids, subsequently abandoned this view and substituted for it a theory of a functional relationship between the two bodies.[51] This theory is based upon three kinds of proofs. 1. Chemical. Gley finds in the parathyroids of the rabbit about 25 times more iodine than in the thyroid, in the dog six times more. The presence of iodine in the parathyroid has been confirmed by Mendel[52] and by Pagel.[53] These observations tempted Gley[54] to the hypothesis that the parathyroids prepare the secretion, which is then stored in the thyroids and utilised according to the needs of the economy. If the iodine be not rendered harmless by elaboration in the parathyroid (as when these are extirpated) then we get acute symptoms. If the iodine be subjected to preparation in the parathyroid but is not distributed to the body by way of the thyroid (as when this is extirpated) then we get nutritive troubles from the absence of assimilable iodine in the body. 2. Physiological. Very occasionally complete parathyroidectomy, leaving the thyroid *in situ*, is stated to give rise not to acute symptoms but to slowly progressive changes in bodily nutrition, resembling those produced by simple thyroidectomy (leaving one or more parathyroids behind). It is alleged by Lusena[55] and also by Vassale and Generali[56] that simple parathyroidectomy kills more rapidly than thyro-parathyroidectomy.[57] This is explained by Vassale and Generali by supposing that when the parathyroids are removed the animal is in a toxic condition, which is the more marked when the nutritive changes of the body generally are more pronounced. The tetany then will be more or less serious according as the thyroid is more or less active and therefore logically will be much less marked after ablation of the gland. 3. Histological. According to Edmunds and Vassale and Generali[58] there is a disappearance of the colloid substance in the thyroid after removal of the parathyroids. These arguments are put forward by Gley to support his theory as to a functional relationship between thyroid and parathyroid. This theory is also held by Jeandelize.[59] The presence of iodine may not after all be a matter of supreme significance for the function of either thyroid or parathyroid. Hutchison[60] says: "One would conclude from the whole evidence that the iodine in the thyroid gland, if it plays an essential part in the activity of the latter at all, does so simply in virtue of the special form of combination in which it is present." He points out that Mirva and Stoltzer[61] found that there was no iodine in the thyroids of young infants or in those of dogs fed exclusively on meat, and concluded that the presence of iodine is not essential for the activity of the gland. But there can be no doubt that there are important morphological and physiological relationships between thyroid and parathyroid. Kishi[62] definitely states, as did the older observers, that the parathyroids are not separate and independent organs but are embryonic thyroids. Vincent and Jolly[63] found that parathyroids left behind after thyroidectomy can under certain conditions develop in the direction of thyroid tissue and a functional replacement also takes place.[64] The two structures are derived from very similar sources and even in the fully developed state there is no fundamental difference between their constituent cells. The intervesicular tissue of the thyroid is practically identical with parathyroid, and parathyroid has only to contain colloid vesicles in order to constitute itself thyroid. Dr. Chalmers Watson has recently sent me a slide which shows human "parathyroids" containing some colloid vesicles and this has also, I believe, been previously observed. It is difficult to imagine any other explanation of this occurrence than that thyroid and parathyroid are morphologically and functionally very intimately related to each other.

D. Chemistry of the thyroid.—The question naturally arises, What is the chemical nature of the active principle of the thyroid gland? What is the substance, or what are the substances, manufactured by the thyroid and supplied to the body, the absence of which causes such serious metabolic disturbances in some animals? We may say at once that there is at present no satisfactory answer to the question. Fränkel[65] separated from the gland a crystalline substance having the formula $C_6H_{11}N_3O_5$ which he called *thyreo-antitoxin*. This he thought was the active principle of the organ. In 1895 Baumann[66] discovered the presence of iodine in the thyroid glands and prepared a substance from them containing as much as 9·3 per cent. of iodine. This is an organic compound of iodine. It is prepared by treating thyroids with 10 per cent. sulphuric acid with the aid of heat. On cooling a precipitate comes down which is dissolved in alcohol. From the alcoholic residue the fat is removed with petroleum ether and the substance remaining is dissolved in 10 per cent. caustic soda. The brown solution is precipitated again with sulphuric acid. The product is a brown amorphous substance insoluble in water and soluble with difficulty in alcohol. It is readily soluble in dilute alkalies and is precipitated by acids. It contains no proteid but some phosphorus (0·4–0·5 per cent). [The amount of iodine per gramme of the organ in human adults varies from 0·3 to 0·99.] This substance prepared by Baumann has been put upon the market as thyroiodin by Bayer and Co. of Elberfeld. Baumann and Roos claimed that this was, in fact, the active principle of the thyroid gland; and Hildebrandt[67] finds that thyroiodin alone is able to counteract the effects of thyroidectomy and to keep the animal alive. It represents the physiologically active principle of the thyroid gland. This author states that the excretion of albumin and sugar in the urine which accompanies the severe symptoms induced by thyroidectomy ceases under the administration of thyroiodin. Other salts of iodine are unable to prevent the onset of symptoms. As to the fate of the iodine of the thyroiodin he finds that it is held back in the body with extreme ease, while simple iodine preparations appear almost at once in the urine. He lays special stress on the fact that thyroiodin does not appear in the urine of a dog from whom the thyroid has been removed; hence other organs of the body must have the power of holding back the thyroiodin. On the other hand, the building up of the complicated combination present in thyroiodin from the simple iodine is to be looked upon as a specific function of the thyroid gland.[68]

---

functional importance would urge that more parathyroid material is required when administered in this manner than is naturally included in the extracts.

[68] So also Blumreich and Jacoby (Archiv für *Physiologie*, 1896, 64)

Baumann showed a rise of the iodine present in the thyroids of animals treated with potassium iodide or iodoform. Vassale[69] held that intravenous injection of thyroid extract prevented the ill-effects of thyroidectomy but Thuneberg[70] held the opposite view. Baumann and Roos,[71] Baumann and Goldmann,[72] and Hofmeister[73] agree that thyroiodin is able to supply the functions of the gland after removal, but Gottlieb[74] and Notkin[75] could not confirm this result. Wormser[76] believed that none of the single substances obtained from the thyroid was able to replace its functions and thought it necessary to give them all at the same time if they were to serve as substitute for the normal internal secretion of the gland. Stabel[77] at about the same time came to the conclusion that neither thyroiodin nor thyroid gland substance was able to keep dogs alive after thyroidectomy. So also Pugliese.[78] This observer removed the thyroids from 12 dogs and fed the animals on thyroid "tabloids." All the animals died at 2, 3, 6, 7, 12, 16, 23, 30, and 68 days after the operation, the earlier ones from tetanic symptoms, the later ones from cachexia. Pugliese's observations then stand in opposition to those of Gottlieb and Wormser, but in agreement with those of Stabel, and show that the giving of thyroid preparations is in no way able to keep an animal alive after thyroidectomy.[79]

It is thus evident that Baumann's thesis as to the identity of his thyroiodin with the actual functionally active principle of the gland has not been sustained by all later observations. At any rate, the statements on this point are very conflicting. Any accounts of beneficial results arising from any kind of treatment after thyroidectomy are to be received with extreme caution, since the results of the operation are so inconstant and symptoms frequently diminish or even disappear in animals which are left entirely without any treatment.[80] But there are other objections to Baumann's theory. Iodine is absent from the thyroids of some animals. Baumann himself states[81] that while the thyroid of a dog fed upon Spratt's dog biscuits contains iodine, this element is absent after a meat diet. In the ox, horse, and pig iodine may be absent or may be present in the merest traces[82]; further, Baumann admits that iodine cannot always be found in the human thyroid. One of Baumann's chief arguments in favour of his view lay in the observation that administration of thyroiodin in cases of goitre causes disappearance of the tumour. But this is a known remedial action of iodine[83] *quâ* iodine and proves nothing as to the therapeutic efficiency of the thyroiodin. Good results have been alleged to follow the administration of various inorganic and organic preparations of iodine[84] and certain sea animals and plants which contain iodine have been used as medicaments, and especially in cases of goitre, for hundreds of years before the discovery of iodine.[85] It is possible, as Bunge[86] suggests, that the organic form of iodine may be more readily absorbed and reach the part where its influence is effective. According to Oswald[87] the iodine of the thyroid gland is bound up with a globulin-like body and the compound is called by him *thyreoglobulin*. This, he says, has all the physiological properties of thyroiodin.[88] From it one can isolate the thyroiodin. The thyreoglobulin forms, along with a nucleo-proteid, the colloid substance of the thyroid vesicles. No chemically pure substance has, however, yet been isolated from the thyroid gland and the presence of the iodine is of problematic significance.[89]

E. Influence of the thyroid upon metabolism.—In the treatment of myxœdema and different forms of goitre, a rapid loss of weight is noted on feeding with thyroid gland substance.[90] This is partly due to loss of subcutaneous tissue, partly to loss of water. Thyroid preparations are used to reduce obesity with good results.[91] In order to explain these effects several series of experiments have been performed, with the object of directly studying the influence of the administration of thyroid glands upon metabolism.

The experiments of Ord and White,[92] Mendel,[93] Napier,[94] and Vermehren[95] pointed to a distinct increase of nitrogen in the urine with a concomitant decrease of weight, pointing to increase of proteid metabolism. But in all these experiments, which were of short duration, the total intake and total output were not accurately determined. Similar results were obtained by Dennig,[96] Bleibtreu and Wendelstadt,[97] Bürger,[98] Roos,[99] Zum Busch,[100] Dinkler,[101] and Georgiewsky.[102] The duration of the experiments here was at most 14 days. Other workers have found little or no increase in nitrogen excretion—e.g., Ewald,[103] in a case of myxœdema. Scholz[104] and Richter[105] found a very small increase in the amount of nitrogen excreted. The nitrogen balance remained positive.

The discovery of iodine in the thyroid gland by Baumann[105] and the isolation of thyroiodin as the probable active principle led observers to test the action of this last upon metabolism. Treupel,[107] Grawitz,[108] David,[109] and Dinkler,[110] by observations on the human subject, and Roos[111] who used a small dog, came to the conclusion that thyroiodin influenced metabolism in the same way as the thyroid gland substance itself in that the body weight diminished and the nitrogen secretion increased.

Some experiments of short duration are recorded directed to the estimation of the oxygen taken in and the carbon dioxide given out during thyroid administration. These respiration experiments were carried out after the Zuntz-Geppert method. Magnus-Levy[112] found in a normal

---

"Die Wirkung der Schilddrüse besteht wahrscheinlich in der Ueberführung einer giftigen in eine ungiftige Substanz; durchaus möglich ist, dass es sich dabei um eine Umwandlung von Iod in Thyroiodin handelt, das dann weitere Wirkungen im Organismus entfalten kann."

[89] I can find nowhere any very definite statement as to the percentage of iodine present in the various organs and tissues of the body. Some isolated observations show that small quantities of iodine can be found in the thymus and pituitary. Drechsel found iodine in organic combination in the skeleton of *Gorgonia cavolinii*, and on decomposing obtained a crystalline amido-acid (iodo-gorgonic acid), $C_4H_8NIO_2$. The same observer also records the discovery of iodine in the hair of a patient who had been treated with iodide of potassium. Drechsel confirms the existence of Baumann's thyroiodin and of Fränkel's thyreo-antitoxin, and adds the discovery of still another crystalline basic substance. Hutchison (loc. cit., supra) finds that the physiological activity is always associated with the iodine-containing substance. It seems that the thyroid has the power of storing up any iodine which may be introduced into the body. man during the exhibition of thyroid glands a not very distinct increase of the oxygen intake and the carbonic acid output. Later experiments by the same author[113] on a myxœdematous patient gave on the other hand an increase of 80 per cent. in the oxygen intake under the influence of thyroid and 43 per cent. under the influence of iodothyrin.

The experiments of Stüve[114] on a healthy man showed an increase of oxygen intake of 20–23 per cent. and a somewhat smaller increase of carbon dioxide excretion. Thide and Nehring[115] also found an increase of oxygen intake amounting to 20 per cent.; the carbon dioxide output was smaller and irregular. The distinct increase of oxidation processes shown in these experiments proves that the greater part of the loss of weight under the influence of thyroid feeding is caused by loss of fat. The question as to whether the proteid is also used up to any extent remains unanswered, for the experiments are of too short a duration to exclude the possibility of the increased nitrogen excretion being due to an increased excretion of urea and other nitrogen-containing compounds already stored up in the organism.

Schöndorff[116] has performed a very careful series of experiments of long duration upon dogs and has reached the conclusion that metabolic processes are distinctly increased by the administration of thyroid substance. There is at first no influence on proteid metabolism, but an increase in nitrogenous excretion from increased elimination of nitrogen-holding extractives already present in the body. The body fat is first used up. After a certain period, however, the proteid is also attacked. On stopping the thyroid administration the metabolism returns to normal, while renewed administration leads to increased nitrogenous excretion.[117]

F. Physiological effects of intravenous and subcutaneous injections of thyroid extracts in the normal animal.—The extraordinary physiological effects produced by the intravenous injection of extracts of the suprarenal medulla[118] have led to numerous experiments with extracts of very many organs and tissues. No effects at all comparable with those of suprarenal medulla are produced by any of them.[119] All tissues yield to normal saline solution or water some substance or substances which lower blood pressure to a greater or less extent. Nervous tissues are the most powerful in this direction, but muscular and glandular tissues have a similar effect.[120] There is at presence no evidence that in any of these cases the action is a specific one. Extracts of thyroid gland, then, in common with other tissue extracts, cause dilatation of peripheral arterioles and lowering of the general blood pressure.[121] What the pharmacologically active substances may be is not yet determined. Hutchison[122] found that injection of a solution of the colloid matter has no effect on blood pressure. Injection of a solution of the extractives produces a decided fall, the degree of the latter being proportional to the strength of the solution of extractives employed. A solution of the mineral ingredients contained in the solution of extractives produces a slight fall, but not nearly sufficient to account for the lowering of blood pressure which follows injection of the extractives.[123] This observer did not succeed in producing intravascular clotting in rabbits by the injection of the colloid matter.

Subcutaneously injected extracts of the thyroid gland produce no very striking effects; there is a slight stimulating action such as one gets with other organs and tissues. Oliver and Schäfer[124] found no change in the heart-beat as the result of injection of thyroid extract.[125] Baumann's thyroiodin appears to have no effect on the heart.[126] It has been alleged that the resistance to fatigue of the voluntary muscles is increased by the administration of thyroiodin.[127] Cleghorn,[128] who performed his experiments upon the isolated mammalian heart, found that thyroid extracts augment the force and slightly quicken the rate of contraction, but with larger doses the effect was reversed. This observer also obtained similar results with thyroiodin but not with iodine itself.

Extracts of parathyroid injected intravenously produce a fairly marked lowering of the blood pressure. Subcutaneously, so far as I am aware, they have not been tested.

G. Theories as to the function of the thyroids and parathyroids.—The facts detailed above point to the theory that the thyroid gland furnishes in the form of an internal secretion some substance or substances which are in some animals essential for the maintenance of health. The results of extirpation in young animals, the effects of thyroid deficiency in human beings, combined with the beneficial effects of grafting and opotherapy, are strong arguments in favour of this view. A different theory is held by many writers, who are inclined, as also in the case of the suprarenal capsules, to believe that the gland has the function of destroying toxic products of metabolism.[129] It is possible, of course, that both theories may be correct, though the fact that such a small quantity of tissue is sufficient to fulfil the functions of the organ seems to point to the internal secretion as the more probable. Bunge[130] believes that the active substance is probably of the nature of a ferment.

The old theory of Simon[131] that the thyroid regulates the blood-supply to the brain, has found some modern supporters. The remarkably large supply of blood to the organ and the intimate anatomical relations subsisting between its arteries and those which supply the blood to the brain, have induced Stahel[132] and Waldeyer[133] to agree with the view of Simon. But the idea has been most fully developed by Cyon from the experimental side. He concludes that the function of the thyroid consists in the formation of a substance—thyroiodin—whose duty is to maintain in good order the regulating nervous mechanism of the heart.[134]

With regard to the parathyroids, it will be seen from what has been said above that they cannot be looked upon as organs independent of the thyroid. We must, in fact, look upon thyroids and parathyroids as constituting one apparatus.

[117] The effects of thyroid and parathyroid feeding upon metabolism have been recently studied by Easterbrook (THE LANCET, August 27th, 1898, p. 546; Brit. Med. Jour., Sept. 22nd, 1900; Scottish Medical and Surgical Journal, November and December, 1900), in the healthy subject and in patients suffering from mental diseases. This observer finds that there are considerable loss of weight, some pyrexia, and increased perspiration. The blood shows diminution in the hæmoglobin and to a greater extent in the red cells and slight leucocytosis. There were headaches, pains, tinglings, and prickings, as well as tremors of the face, fingers, and limbs. There were also weakness and a feeling of exhaustion. The urinary nitrogen was much increased. The thyroid acted, in fact, as a profound katabolic stimulant. The parathyroids produced no effects. Breisacher (Journal of the American Medical Association, 1903, vol. lix. p. 556) states that all dogs from which the thyroid has been removed die when fed upon meat or meat broth, while 30 per cent. of the animals fed upon milk and eggs remain normal. This had led physicians to treat various diseases of the thyroid, such as myxœdema and Basedow's disease, by prescribing a diet consisting chiefly or entirely of milk, eggs, and vegetables See, however, Ughetti (Riforma Medica, December, 1892, vol. iv., p. 675). According to Lanz (Correspondenzblatt für Schweizer Aerzte, 1895, Jahrgang xxv., p 293) the subcutaneous injection of thyroid juice in normal animals brings about atrophy of the gland (!).

FRICTIONAL ELECTRICITY: A FACTOR IN CAISSON DISEASE.

BY GEORGE W. F. MACNAUGHTON, M.D. EDIN., M.R.C.P. LOND.,
PHYSICIAN TO THE KENSINGTON GENERAL HOSPITAL.

PERHAPS no malady presents such a number of apparently anomalous symptoms and signs as caisson disease, named also by those who work in compressed air "bends." The latter term suggests the all-flexed position which the sufferer typically assumes. Attacks may occur (*a*) in the caisson, rare; (*b*) immediately on quitting, *not so* rare; (*c*) some hours afterwards, usual; or (*d*) not uncommonly for two or three days after the exposure to compression. We will consider for the purposes of description a delayed case. The individual has a depressed, listless appearance, *the eyes are dull and encircled* by dark lines, and the skin of the face is dry, inelastic, and of a yellowish tinge. The facies is distinctive and once noted is readily recognised. Movements are slow and the sufferer complains of general malaise with slight flying pains; he lacks energy and the power of concentration. This stage may pass off, but may not, and without the person re-entering *compressed air*, especially if he be subjected to excessive bodily strain or mental, more acute symptoms arise *preceded* by a short interval of drowsiness and yawning. Following natural promptings, rest is sought; then, when the body becomes warm, *instead of composure* and sleep, aching commences in the back and loins, involuntary upward and forward *movements* of the shoulders occur, the elbow-joints become semi-flexed, with the forearms midway between supination and pronation, the hands clench themselves, while the trunk inclines forwards, the *thighs bend towards the abdomen*, and the legs are also flexed. The muscles of the back are thrown into tonic contraction in groups or singly. The abdominal walls become tense, accompanied by the peculiar sensation that they are describing *semicircles in the air at* some *distance* from the body. Intestinal peristalsis is exaggerated and if defæcation takes place the contents of the *rectum* are expelled so forcibly that the pelvic viscera threaten to follow. Emptying the bladder conveys an unusual sense *of relief*. These motor spasms last from a few seconds to as many minutes, and are accompanied by acute cramping *pains* in the joints and muscles. There is swimming in the head, with constriction at the back of the ears and in the *post-temporal* regions. The thoughts are scattered over wide fields and the ideas are not consecutive. *These mental vagaries* can be controlled by conscious effort. There is no rise of *temperature*; palpitation with high tension pulse is present.

The foregoing are indicative of the irritant or first stage of caisson disease and most cases do not go beyond this, recovery taking place in from two to six or eight days. The graver series of symptoms, monoplegias, *paraplegias*, of a transient or permanent nature, with or without loss of sensation and consciousness, are *significant of the* exhaustion or second stage. These are due to electrical stimulation, while other signs, such as pallor of the skin, hæmorrhagic spots, spitting of blood, rupture of the tympanum, and dyspnœa, are attributable *to the direct influence* of increased atmospheric pressure, although these causes may overlap and coöperate.

The work of a caissonier, which requires prolonged muscular effort, accelerating the return circulation in the *muscles* of the *extremities* and trunk, causes a repletion of the visceral veins and those of the cerebro-spinal axis. Add to this the pressure of one or two extra atmospheres upon the *capillaries* of the body surface and the tension is still further abnormally raised in deeper tissues. Although the cranium can only accommodate a definite amount of *fluid*, the spinal column and its contents are not so constituted; here the thin-walled venules, inclosed by the inelastic perilymphatics, are especially liable to become over-distended through this increased tension; this creates local pressure and interference with the nutriment of the nerve cells, owing to the accumulation of the products of metabolism in the perilymph and in the protoplasmic elements. There is local rise of acidity, which is a stimulant to the discharge of energy by these cells. This energising is probably assimilated by that required to accomplish work.

There is no reason further to believe that the accumulation of carbonic acid and the anthropotoxins (which is guarded against) has any greater effect in the caissons *per se* than it has in any other confined *space* where the air is not compressed, although "bends" have been ascribed to this agency. It is otherwise when the caisson atmosphere, as at present engendered, is charged with electricity, carried by the droplets of water vapour, and when the electric potential in a moderate-sized caisson may be compared in amount with that of a *flash of lightning*. The worker in this atmosphere accumulates upon the body surface electricity which either by directly permeating the tissues reaches, amongst others, the nerve centres, or by acting upon the peripheral nerve filaments or muscle end plates stimulates these centres from the afferent side. Although the amount of electricity be insufficient to produce a conscious effect upon the *exterior*, the nerve cells are thrown into a state of excessive activity, manifesting itself in discharges of a purposeless motor and sensory nature, the "bends" or otherwise the individual becoming polarised in the caisson. When decompression in the air lock takes place, the rapid decomposition of electricity accompanying this and the fall of electric potential cause a similar effect.

But why should the nerves which control the flexors be specially affected? They are not so, but these *form* a greater and more highly organised part of the nervous system than the areas which subserve extension, and the excitant being equal and general the flexion manifestations are thus the greater. The personal equation is an important factor, as in some individuals an exposure to an extra pressure of 12 pounds per square inch for an hour is sufficient to cause an incidence of caisson disease; in others exposure to the compressed air for 40 minutes at 18 pounds *added pressure* has been followed by an attack.

The electricity of the caisson atmosphere is hydro-electric in origin, and the means at present in vogue of compressing and conducting air into the workings is an enlarged continuous performance of the Armstrong-Faraday experiment, with moist air instead of steam. That this is so, without going into the full details of the steam or dynamo compressing engines, the following details show. *Ordinary atmospheric* air is sucked in through valvular openings and is simultaneously compressed and propelled along 15, 20, or 30 feet of plain metal tube into the cooling tank, and it is in this tubing that the electricity is chiefly generated by the friction of the more or less moist air against its walls. The effect of this is to produce so great a rise of temperature, even at 12 pounds added pressure, that it is impossible to place the hand upon the outside for more than the fraction of a second, while a greater compression causes, roughly speaking, a correspondingly high degree of temperature. Reaching these tanks, which are large iron cylinders immersed in cisterns and with cold water flowing over them from above, the air is *cooled* and passed on by metal tubes of varying diameter to the workers. After cooling, the electrical changes taking place in the air are unimportant, but obviously two molecules of air at 15 pounds added pressure or three at 20 pounds pressure occupy the *space* of one molecule of atmospheric air; this, which at ordinary temperature and pressure *is a* feeble conductor to electricity, obtains under pressure a *heightened* conducting power. This power is greater if the air be humid, as after *rain, and* still more so if the humidity be constant, as at sea or riverside working. That this reasoning is not merely theoretical has been demonstrated by a Kelvin galvanometer, for when the same men were tested before going into the working and an hour after being there the deflexions of the mirror were in all cases much increased in the latter. These observations were made upon men some of whom were labouring and upon some who did not perform any manual work. With a gold-leaf electroscope, after a slight primary divergence, the leaves *folded together* and remained stationary, refusing to respond to either positive or negative stimulation. During these observations care was taken to exclude fallacies as far as possible.

As a conclusion *to* the above, in order to hinder or to minimise this generation of electricity in the process of compression, it would appear that the air allowed to enter the intake of the compressor should be absolutely dry. This result might be obtained by its passage through heated tubes arranged in a furnace like those of locomotive engine boilers or one of the *heat economisers* in general use.

For small quantities of air chemical agents, such as calcic chloride or sulphuric acid on pumice stone, might be employed but the expense and difficulty of working with these prevent their application in dealing with large quantities. If impossible to dry the air another means of modifying the generation of frictional electricity would be to line the conducting iron tube, at least as far as the cooling tank, with non-electrical material, such as asbestos packing, earthenware, or highly vulcanised · vulcanite, while the ends of the compressing pistons and their receivers should either be of a non-metallic substance or capped with such. Drying air, however, is the method which commends itself for saving expense, as water vapour expanding into steam offers a marked opposition to compression. One drawback to this drying process is that perfectly dry air is irritating to the lungs, eyes, and other exposed mucous membranes, so that before being distributed to the caissons it would be necessary to let it lick up moisture either by bubbling through or passing over the surface of water in a tank placed near the inlets. Passing through water would be the better means because impurities would be washed out thereby.

With regard to the various views expressed as to the causes of caisson disease, it is difficult to explain an attack occurring in a man after 70 minutes' exposure to 18 pounds added pressure by one that attributes the malady to the escape of bubbles of free nitrogen into the blood, the gas having previously been dissolved therein, and still more so when the incidence is delayed by two and a half days after the exposure. Again, ponies are employed for eight hours daily in pulling wagons in the caissons, and despite their relatively large lungs and cranial air spaces they do not show symptoms attributable to disengagement of nitrogen bubbles, which would naturally be expected were "bends" due to a solution and a subsequent dissolution of this gas in the circulating fluids, but this immunity is explicable by their thick hides being able to resist the effects of compression, while their hairy coverings act as non-conductors of electricity.

Bubbles of air may be demonstrable in the tissues of frogs which have been placed under increased atmospheric pressure, but it is not logical to conclude that the same will apply to man, because in amphibians the skin possesses a respiratory function, while under it lie the sub-epidermal lymph sacs, inflatable potential spaces, forming a direct route for the passage of gas into their blood. In mammals, when the blood is normally aerated, it seems physiologically impossible to bring the respiratory interchanges under the dictum of Dalton's law, and what is claimed with regard to caisson disease as due to the absorption and defervescence of nitrogen gas under compression and subsequent decompression is quite explicable by a rise and rapid fall of electric tension. In attacks of caisson disease where paralysis, coma, and death occur, and where, on post-mortem examination, rents or other gross lesions are present in the substance of the spinal marrow or brain, these are probably caused by rupture or the pressure effects of the over-distended perilymphatics, this over-distension being, as already indicated, attributable to the combination of pressure upon the body surface and to the effect of muscular action upon the circulation. There is great similarity between the symptoms of a non-fatal lightning stroke and an attack of caisson disease, while the return shock of lightning is physically comparable to the changes which follow a too rapid decompression after long exposure in the caisson atmosphere. From this reasoning the use of a medical lock for recompressing the patient is therapeutically rational, while under this category cannabis indica, salicin, salicylates and allies, from their known sedative and analgesic effects, are to be placed.

Thanks are due to Messrs. Walter Scott and Middleton, the contractors of the Euston Extension, *Central London* Railway, for their permission to make observations.

Lower Belgrave-street, S.W.

ANALYSIS OF TINNED MEAT.—The Wiltshire county council, at its meeting held on August 8th, approved of the action of the county medical officer of health in declining to undertake analysis of samples of tinned meats submitted to him by the direction of the Bradford-on-Avon urban council. The county council considers that the protection of the public against tinned meat which is unfit for food is a matter within the jurisdiction of the urban council, and that no action on the part of the county council is called for.

OBSERVATIONS ON THE ACTION OF STRONTIUM SALTS ON THE COAGULABILITY OF THE BLOOD.

BY J. B. NIAS, M.D. OXON., M.R.C.P. LOND.

THE following observations were made in the Pathological Laboratory of St. Mary's Hospital at intervals during the past year by the kind permission of Sir A. E. Wright, and were mainly carried out on a patient under his care whom I was allowed to examine with considerable frequency. They are intended to supplement a paper which appeared in THE LANCET of Oct. 14th last by Sir A. E. Wright and Dr. W. E. Paramore on the Therapeutics of Blood Coagulation, and another which appeared in the following number by Sir A. E. Wright and Dr. G. W. Ross on the Action of Calcium and Magnesium Compounds in the Treatment of Physiological Albuminuria. The observations recorded were for the most part simultaneous in point of time with those of Dr. Paramore, he taking the action of calcium and magnesium and I that of strontium by agreement, so as not to interfere with one another.

The patient on whom I made these observations is a sufferer from hæmophilia, for whom it became desirable to find a drug as a substitute for calcium, as repeated observation by Sir A. E. Wright and myself established that in his case calcium salts were not absorbed when administered by the mouth. This is a detail which seemed to me worth working out in the interest of general therapeutics, as it is probable that there are other drugs with regard to which similar disabilities may exist and have to be overcome. I therefore took considerable pains to establish the fact in the present instance and in this I think I have succeeded, the result of my observations being to prove that the subject in question can absorb with facility, when they are given by the mouth, the soluble salts of strontium and magnesium while refractory to those of calcium.

The condition for which it was required to improve the coagulating power of this man's blood is a periodical oozing of blood from the alveoli of some of his teeth with which it does not appear safe to deal surgically. Generally the time taken by his blood to coagulate in a Wright's capillary tube is two and three-quarter minutes or so at blood heat, the normal for that temperature being two minutes or rather less. At times he suffers from an attack of boils and then the extra amount of nucleo-proteid circulating in the blood has the effect of raising its coagulability to the normal or above, and the hæmorrhage is then suspended, to recur again on convalescence as the coagulating power falls. Sir A. E. Wright has tried to obtain a similar result artificially with such substances as peptone and thymus gland but only with moderate success, and the desideratum therefore seemed to be to furnish the patient with a drug that would have a prompt effect when taken by the mouth whenever a hæmorrhage came on without waiting for the time to visit the hospital. In this direction some advantage has been gained by means of the present research.

After it had been established that the patient could not absorb calcium salts by the mouth the idea occurred to me that a compound of greater molecular weight but otherwise possessed of the same properties would be indicated for trial, as presumably traversing a mucous membrane more easily; and my attention therefore turned in the first instance to strontium, of which the molecular weight is to calcium as 87 to 40; but inasmuch as subsequent observation showed that the patient absorbed equally well the salts of magnesium of which the molecular weight is only 24 I fear that the hypothesis has no foundation. Nevertheless, as the starting point of the present investigation it requires to be mentioned; but I am not able at present to throw any further light on the cause of this curious and, I think, generally unrecognised condition that an individual should be able to absorb with facility two only out of three closely allied metals when by the generality of persons all three are equally easily absorbed. As I have said, such a peculiarity may obtain in other cases, and as a matter of fact another instance of the same kind is recorded in the paper of Wright and Paramore in the person of an individual, under the initials A. E. W., who can absorb the salts of magnesium but not those of calcium.

Among the salts of strontium the bromide, of course, has had considerable vogue in epilepsy and other occasional uses of the metal are recorded in pharmacological literature; but no definite mode of action or the possession of any particular activity by strontium as a base seems as yet to be recognised by medical practitioners. Yet Arthus and Pagès in their classical work on the process of coagulation expressly state that strontium salts will replace those of calcium in restoring its coagulability to oxalated blood.[1] No one seems, as I say, to have ascribed to this palpable activity the medical benefits asserted to have been obtained by the use of strontium. The authors referred to curiously enough deny a similar property to magnesium, a statement which in the face of Wright and Paramore's results can only have a partial application. They say: "Les sels de strontium peuvent comme les sels de calcium produire la coagulation. Les sels de barium et de magnesium sont impuissants à faire coaguler le sang decalcifié." To Wright and Paramore, as far as I can see, belongs the merit of first demonstrating that an important effect of magnesium when absorbed into the system is that of increasing the coagulating power of the blood, the statement of Arthus and Pagès being either a slip of the pen or only applicable to the blood of animals with which they worked. In the case of milk[2] they say, on the other hand, "Les sels de barium et de magnesium par exemple se comportent comme les sels de calcium." By employing one of Wright's methods it is easy to demonstrate that if blood drawn from the finger be mixed with just enough of a solution of ammonium oxalate (in physiological salt solution) to prevent coagulation and then a little of this mixture be aspirated into a capillary tube with a fragment or two of a calcium or magnesium salt, coagulation will set in as rapidly with the magnesium as with the calcium. Strontium shows a similar but decidedly weaker action, often allowing a partial subsidence of red corpuscles before the clot forms, and barium I have not noticed to have any activity in this direction at all.

An important practical application of the strontium salts in medicine was made in the year after the publication of Arthus and Pagès's research but without apparently any attribution of the results obtained to the properties which they had demonstrated. In 1891 Dujardin-Beaumetz and others in Paris gave an exhaustive trial to the action of lactate of strontium in cases of albuminuria, instigated thereto by Laborde who had shown the harmlessness of strontium salts on dogs. In Vol. XIV. of the *Progrès Médical* (1891, pp. 313, 409) will be found abstracts of communications made to the Société de Thérapeutique with regard to this point, from which it appears that lactate of strontium given in doses up to six grammes per diem will produce a great diminution in the amount of albumin excreted in cases of "parenchymatous and desquamative nephritis, but not in the interstitial form." This treatment seems to have been subsequently abandoned and certainly has never come into general use, perhaps from proving only palliative and still more I imagine because no intelligible mode of action was assigned to the drug by the experimenters. On this point they all express themselves very vaguely. Later still, Ried is quoted in THE LANCET of Oct. 27th, 1894, from the *Centralblatt für Gesammte Therapie*, as having found that "lactate of strontium, which is certainly an excellent diuretic, is beneficial in a large proportion of cases of Bright's disease, at all events when no sclerosis of the kidney has taken place," but he too only vaguely conjectures its mode of action Yet, as confirming the more advanced results of Wright and Ross with regard to physiological albuminuria, these bygone empirical observations have their value and ought to stimulate fresh workers to the elucidation of an important problem.

I must now pass on to the record of my own experiments with the lactate of strontium which, beginning in the early part of last year, have been continued up to the present as opportunity offered.

1905. Feb 8th.—The patient at this date was suffering from daily oozing of blood from his gums. After the coagulation time of his blood had been found to be 2 minutes 16 seconds, he took a dose of four grammes of calcium lactate, an amount sufficient to produce a decided effect on most persons; but after 40 minutes, when the coagulation time was estimated again, no change could be detected. On Feb. 10th the coagulation time was two minutes 30 seconds; and therefore no effect remained from the previous dose (compare this with the figures of Wright and Paramore, *loc. cit.*). The strength of oxalate solution required in equal quantity to inhibit coagulation according to Wright's standard was $\frac{1}{1200}$, so that there was no actual deficiency of lime in the blood but the object in view was to force it above the normal. Another line of treatment was adopted for the time being as the patient continued to bleed. On Feb. 17th the patient was found to be no better and his coagulation time had receded to 2 minutes 50 seconds. Four grammes of calcium lactate were again given and again 45 minutes later no improvement could be detected in the coagulating power. On Feb. 24th the coagulation time was still longer—namely, three minutes. At 6 15 P.M. an injection of half a gramme of calcium lactate in salt solution was made into the flank. The coagulation time was then taken every five minutes so as to ascertain the rate of absorption; 30 minutes after the injection it began to shorten, at 7 P.M. reaching 2 minutes 15 seconds, and at 7.15 two minutes precisely. At this figure it remained to the end of the observation, the rapid improvement minute by minute being very interesting to watch. On March 15th the patient was somewhat better as regards the oozing of blood. Two grains only of calcium lactate were injected hypodermically, an intermediate injection of ten grains having apparently got into dense fascia and produced local coagulative effects, ending in great pain and collapse. Most certainly this risk attends all hypodermic injection of coagulative salts. The small quantity given on the present occasion without any injury was sufficient to reduce the coagulation time in the course of one hour from 2 minutes 35 seconds to 2 minutes 5 seconds and thus it became clear that the obstacle to the entry of lime salts into this man's blood resided in his alimentary canal. It was at this point that the idea was conceived of looking for an alternative drug and for the time being Sir A. E. Wright put the patient on thymus gland, which had previously been found useful. By July 21st, having become acquainted with the pharmacological literature of strontium, I obtained a supply of the lactate and began experimenting on myself. On this date, my blood coagulating in 2 minutes 5 seconds, I took one gramme at 4.15 P.M. By 5.15 the time of coagulation was reduced to 1 minute 30 seconds, but by 6.45 it had again increased to 1 minute 50 seconds and at 7 P.M had reached the original figure of 2 minutes 5 seconds, thus showing that the effect of strontium, though typical and decisive, has a certain fugitive character, not so marked in calcium and magnesium. Possibly this is due to the fact that strontium is not a normal ingredient of the blood; but this fugitiveness is not always to be noted, as will be seen hereafter, nor can I exactly specify the conditions under which it appears. On July 24th I took a smaller dose—two thirds of a gramme of strontium lactate. At 6 P.M. my coagulation time was 1 minute 45 seconds, by 6.40 this had been reduced to 1 minute 10 seconds, and an hour later, at 7.40, had begun to recede again, being 1 minute 20 seconds. The observation was here stopped for dinner and I may say that observations of this detailed character have to be limited to the time between meals or changes of occupation if they are to have any value. On August 14th my time was rather longer than usual—namely, 2 minutes 20 seconds. At 6 P.M. half a gramme only of the lactate was taken and at 6.50 the time had become reduced to 1 minute 45 seconds, extending again by 7.20 P.M. to 2 minutes exactly. For practical purposes it was deduced from these experiments that a proper dose would be from one to two grammes. On August 23rd the first opportunity occurred for testing Sir A. E. Wright's patient with the lactate of strontium. He had now for some months been taking 35 grains of thymus extract daily and was consequently in much better condition, though not altogether exempt from hæmorrhage. At 4.30 P.M., when his coagulation time had been found to be 2 minutes 35 seconds, he received one gramme of strontium lactate and at 5.30 the coagulation time had become reduced to 1 minute 55 seconds, at which it remained to the end of the observation. An improvement of 30 per cent. in coagulating power at the first trial was a welcome contrast to the experiences with calcium. A considerable interval here elapsed owing to my holidays. On Nov. 8th the patient's blood was found to coagulate in 2 minutes 50 seconds and at 4 10 P.M. he had a dose of two grammes of the lactate. By 4.50 the time was reduced to 2 minutes 5 seconds and at 5.20 to 1 minute 50 seconds, when the observation terminated. Again an improvement of 30 per cent. recorded. Nov. 15th.—The joint paper of Wright and Paramore having now appeared and their results therefore available, I thought I would try a comparative test with magnesium, choosing the lactate as preferable for a rapid effect in the place of the more insoluble carbonate. On this occasion the patient's blood coagulated in three minutes exactly. At 4.15 two grammes of the lactate of magnesium were given and by 4.50 the coagulation time was reduced to 2 minutes 25 seconds, and further by 5.20 to 2 minutes 10 seconds. It appeared then that magnesium acted as well on this patient as strontium, producing also an improvement of nearly 30 per cent. Dec. 13th.—As the result of occasional doses of magnesium carbonate prescribed by Sir A. E. Wright the patient had improved perceptibly. An oxalate test showed a strength of $\frac{1}{1050}$ as required to inhibit coagulation. The lactate of strontium was again tried on this occasion, a dose of one gramme being given at 3.50 P.M.; the coagulation time was then 2 minutes 50 seconds. By 5.20 the time had been reduced to 2 minutes and at 6 P.M. to 1 minute only. This excellent result of an improvement of 60 per cent. for the time being in the coagulating power was apparently due to the longer continuance of the present observation and might possibly have been before recorded if the times available had allowed. No fugitiveness in the effect was to be noted on this occasion; I cannot say why. On Dec. 20th and Jan. 3rd and 5th of the present year fresh trials were made to reaffirm the inability of this patient to assimilate calcium; the results were exactly as before, at the most on the third occasion an improvement of 15 seconds being noted after the lapse of three hours, after a dose of two grammes of calcium lactate. The treatment of hæmophilia not being the special object of this paper I need not detail the further observations made on this man except to say that he has of late been supplied with powders of strontium or magnesium lactate for self-administration in emergencies and as a result he has been able to report to me on more than one occasion that hæmorrhages have ceased within 12 hours instead of going on for days. Perfect success, however, is not always obtained, as might be expected with such a difficult pathological condition to contend with, but it may be affirmed that something has been accomplished for his comfort so far.

[2] Ibid, p. 339.

Conclusion.—From these experiments I think it is clearly established that the lactates of both strontium and magnesium in doses of from one to two grammes are serviceable substitutes for the salts of calcium when the latter are not absorbed from the alimentary canal, thus enabling us to dispense with the dangerous practice of hypodermic injection which my experience does not show to have any advantage in speediness of action.

These observations also, I think, enforce the old lesson of the complexity of vital action with which the physician has to contend and show how the recognition of minute differences and the mastery of minute details must not be avoided if one wishes to triumph in a difficult art like medicine. I hope to see someone else with the requisite opportunities taking up the question of albuminuria and its treatment with these coagulative salts, when probably other differences in their action will be demonstrated.

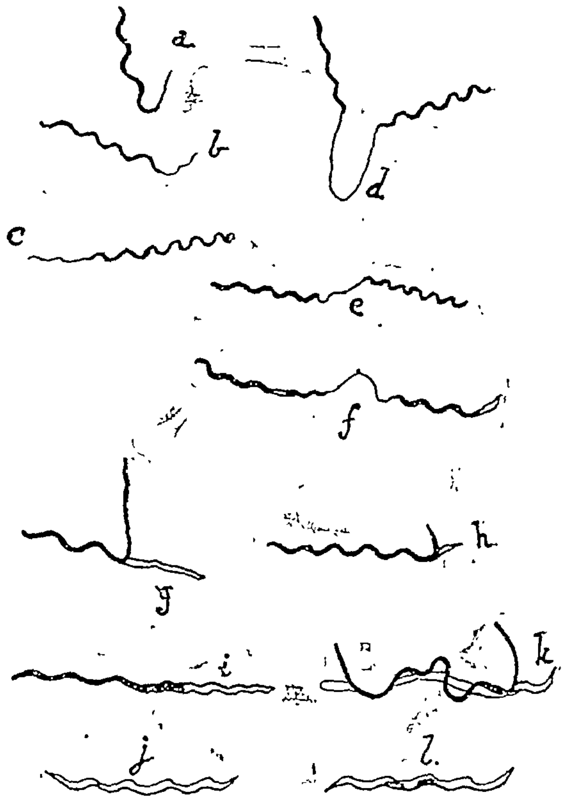
A NOTE ON THE STRUCTURE OF SPIROCHÆTA DUTTONI.

By J. W. W. STEPHENS, M.D., D.P.H. CANTAB.,
LECTURER ON TROPICAL MEDICINE, UNIVERSITY OF LIVERPOOL.

WHILE engaged in investigating some of the methods in use for staining bacterial flagella I was led to apply these methods to the staining of the spirochæta of African tick fever. It will be unnecessary here to review the results obtained with other spirochætæ by other observers, as these questions will be fully dealt with shortly by Dr. J. L. Todd and Dr. A. Breinl, to whom I am much indebted for a plentiful supply of material. The difficulties of applying the silver method of staining flagella described by me in the Thompson-Yates Laboratory Reports for 1903, Vol. V., Part I., to spirochætæ contained in an albuminous fluid like blood plasma are so considerable that I abandoned this method after many unsuccessful attempts to wash the spirochætæ by centrifugalisation sufficiently clean to get good preparations. I, however, succeeded by this method in demonstrating in some specimens a terminal flagellum.

Another method, as yet unpublished but similar in principle to Löffler's method, has given me beautiful results with different bacterial flagella. It is the results obtained with this method that I think are of interest. Here again the spirochætæ were centrifugalised and washed in normal salt solution three or four times. Films were then made of the sediment and after mordanting stained with gentian violet. The forms observed under an ordinary oil-immersion objective were the following: 1. Forms showing a terminal flagellum (*a*, *b*, *c*). So far I have not found a flagellum at each end or any indication of peritrichous flagella. 2. "Linked" forms (*d*, *e*, *f*)—i.e., two ordinary spirochætæ joined by a thin intervening portion resembling the flagellum in appearance but of very variable length. 3. "Eviscerated" forms (*g*, *h*, *i*, *k*), probably due to mechanical and chemical action. Many of these forms were seen. They presented two portions: (1) the partly or even completely eviscerated "core" often of a peculiar rigid appearance staining deeply and uniformly; and (2) the faintly staining remaining "sheath" still retaining the undulations of the normal spirochæta. Not uncommonly faintly staining "sheaths" (*j*, *l*) were found devoid of any core but I have not observed an empty sheath with a flagellum attached to it. These terms I use in a purely descriptive sense; their interpretation I must leave to those engaged in the special study of spirochætæ. It seems to me, however, that these forms, especially the "eviscerated" ones, have considerable bearing on the question of the bacterial or protozoan nature of spirochætæ.



Diagrammatic representations of various forms of spirochæta Duttoni: *a*, *b*, *c*, Spirochætæ showing a terminal flagellum. *d*, *e*, *f*, "Linked" forms. *g*, *h*, *i*, *k*, "Eviscerated" forms. *j*, *l*, Empty "sheaths."

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF MITRAL STENOSIS; DEATH FROM EMBOLISM OF SIX MAIN ARTERIES.

BY RICHARD S. ROPER, M.R.C.S. ENG., L.R.C.P. LOND.

A MAN, aged 27 years, was admitted to the St. Marylebone Infirmary on Oct. 26th, 1905, suffering from cardiac disease and bronchitis. He had had rheumatic fever twice. On admission he complained of cough but otherwise seemed in fair health. On examination there were a few râles and rhonchi scattered over both lungs. The cardiac area of dulness was increased and on auscultation well-marked systolic and mid-diastolic bruits were heard at the apex. No other bruits were heard. The pulse was regular and of good volume. The liver was not enlarged, neither was there any ascites, œdema, or other sign of failing compensation. The patient was kept in bed for a month and as at the end of that time all physical signs in the lungs had subsided he was allowed up and by Dec. 7th was up all day.

On Dec. 7th, at 4.45 P.M., while in the day-room the patient suddenly became very ill and was at once removed to bed. When examined he was blue, pulseless, cold, and clammy, and was struggling vigorously, and at the same time complained of great pain in his legs. The heart was beating regularly and at normal rate but no bruits could be heard. At 7 P.M. the general appearance of the patient was much the same and the condition of collapse was very little improved. He still complained of great pain in the knees and abdomen. Neither tibial pulse could be felt nor was there any pulse at the left wrist. The left femoral artery could be felt pulsating just below Poupart's ligament. Both lower limbs and the left arm were paralysed. There was anæsthesia of the legs as far up as Poupart's ligament. The abdomen was slightly distended. At no time was he unconscious and his mental condition was quite clear. A sixth of a grain of morphine acetate was given and at 10 P.M. he had somewhat recovered and had less pain. At this time his face was a natural colour, the collapse had passed off, and he was warm. He was still unable to move his left arm but motor power and sensation had returned to the lower limbs. The right radial was the only artery felt pulsating in the limbs. The abdomen now was very distended and a copious blood-stained motion was passed. Several ounces of blood were passed per rectum until death, which took place at 4 A.M. on Dec. 8th.

A post-mortem examination was made seven hours after death. There was hypertrophy of the left auricle and ventricle with marked stenosis of the mitral orifice. The latter just admitted the tip of one finger. Recent vegetations were present on the inner wall of the left auricle of the size of a pea. No ante-mortem clot was to be seen. The small intestines were distended and anæmic. Embolism of the following arteries was found: both common femorals, with ante-mortem clot extending as far as the popliteal artery; the right internal iliac at its bifurcation; the right renal at its division; the superior mesenteric just below the middle colic branch; and the left brachial at the origin of the superior profunda. No other pathological condition was found in any organ.

I am indebted to Mr. J. R. Lunn, medical superintendent, for permission to publish this case.

Notting Hill, W.

A CASE OF LEUKÆMIA SUCCESSFULLY TREATED WITH ARSENIC.

BY FRANK LINDSAY DICKSON, M.B., CH.B. GLASG.

THE patient in the following case was a man, aged 24 years, who came to me on May 30th complaining of pain in the back, slight headache, and general debility. His temperature was 99·6° F. and I gave him a saline mixture with orders to rest for a few days. He returned three days later and stated that the pain in the back was better but that he felt very weak. His temperature was normal and I treated the case as debility following influenza, prescribing compound syrup of the hypophosphites and cod-liver oil. At the same time I noticed a slight swelling of one of the deep cervical glands. This was hard, freely moveable, and quite painless. The patient then took to his bed, there being great prostration. The glandular enlargement increased until the swelling was of about the size of a hen's egg. His temperature remained normal and there was no improvement in his general condition.

On the evening of June 6th I found that the inguinal, right axillary, and post-cervical glands were slightly enlarged; the splenic area of dulness was slightly increased and pain was induced on pressure over that organ. I was inclined to diagnose the case as one of pseudo-leukæmia, true leukæmia to be left for consideration after examination of the blood, for which purpose I sent him to the Queen's Hospital, Birmingham. The patient was seen by Dr. J. G. Emanuel, who afterwards told me that he was inclined to regard the case as one of mild enteric fever. A blood film was, however, taken and on the next morning I received from Dr. Emanuel a letter from which the following is an extract: "There is a great excess of leucocytes and lymphocytes, the latter predominating. I regard it as being one of those rare cases of acute or subacute lymphatic leukæmia. I expect it will terminate fatally in a few weeks." I examined the blood myself on the following day and found that the white cells were almost as numerous as the red ones. I then commenced to administer liquor arsenicalis, giving five minims three times a day, and the result seemed almost miraculous. After three days the patient "felt much better in himself," the glandular swellings were noticeably less, and I found that there was marked improvement in the condition of the blood. The dose of liquor arsenicalis was increased rapidly until 15 minims were being taken thrice daily, the improvement continuing and no toxic symptoms being produced by the drug. The patient had one attack of epistaxis which weakened him a little; he had, however, been subject to these attacks from childhood. About a fortnight later the glands were practically normal and the blood was, in my opinion, in a like condition. Dr. Emanuel came to see him after I had written my opinion on the subject and took half a dozen films of the blood. His next letter said that "the blood is practically normal."

The dose of arsenic was gradually diminished and on July 6th the patient went to the seaside for a fortnight, taking with him sufficient medicine to last him till his return. I gave him iron in addition to the arsenic as the red blood corpuscles needed a little recruiting. On his return he told me that he felt as well as ever he had done in his life. Two days later he returned to his work as a carpenter and he has remained perfectly well ever since. The only predisposing cause was that some time before the commencement of the illness he had been working about some water-closets of which the drains were obstructed and the odours not ambrosial.

Hay Mills, Birmingham.

A CASE OF RUPTURE OF THE GRAVID FALLOPIAN TUBE.

BY N. J. F. VAZIFDAR.

THE patient was an ayah, aged 25 years, who was admitted into the Sir Jamsetjee Jeejeebhoy Hospital in Bombay on Dec. 9th, 1905, for acute intestinal obstruction. The history of her illness was that on Dec. 6th, whilst micturating, she was suddenly seized with an acute pain in the abdomen after which she vomited and fainted. The pain and vomiting increased and on the 8th the vomited matter became fæcal. There was absolute constipation in addition to which no flatus had been passed since the 6th. On admission she was in a collapsed condition. Her temperature was 97° F., her pulse was 146 per minute and very weak, and her respirations were 48 per minute; the abdomen was much distended all over, tense and hard on palpation, and tympanitic on percussion. There was almost continuous fæcal vomiting. The case being diagnosed as one of acute intestinal obstruction, probably due to a volvulus, a median laparotomy was immediately performed by Lieutenant-Colonel W. H. Quicke, I.M.S., the senior surgeon of the hospital. The abdominal cavity was then found to be full of dark blood and blood clots, and further examination revealed a rupture of the right Fallopian tube at its isthmus. The tube was tightly ligatured at its uterine junction, the broad ligament was also ligatured *en masse*, the whole tube with the ovary was removed, and the abdomen was sutured after being flushed with hot normal saline solution. An intravenous injection of 24 ounces of normal saline solution had to be given. The ruptured fœtal membranes with slender chorionic villi were found among the blood clots. The patient was in a very precarious state and had to be supported on stimulating injections for three or four days. She then gradually improved and was discharged recovered on Jan. 29th, 1906.

A very remarkable fact in the case was that the patient on admission showed all the signs and symptoms of acute intestinal obstruction, including extremely severe fæcal vomiting, and the history of her illness as given at the hospital did not contain any clue to its real nature. Owing to the enormous distension of the whole of the abdomen no localised swelling could be distinguished. There was even a history of the patient having a normal menstrual period a week before the illness.

This is the third case of rupture of the gravid Fallopian tube at the end of the fifth week which has been admitted into this hospital during the last two years. All these patients had symptoms and signs pointing most distinctly to intestinal obstruction; and they all had constipation of three or four days' duration, fæcal vomiting, and great distension of the abdomen.

I have to thank Lieutenant-Colonel Quicke for permitting me to report the case.

KIDDERMINSTER INFIRMARY.

TWO UNIQUE CONGENITAL DEFORMITIES IN THE ABDOMEN OF THE SAME PATIENT.

(Under the care of Mr. J. LIONEL STRETTON.)

A BOY, aged five years, was admitted to the Kidderminster Infirmary on July 14th last. He suffered from pain in the abdomen. He vomited some curdled milk soon after admission but after this he retained the milk given to him. His mother stated that he had suffered from pains in the abdomen and occasional vomiting since birth. His bowels were always very constipated. On examination it was noted that he was very thin and emaciated. The abdomen was retracted. On inspection a lump swelled up and became visible in the epigastric region about an inch above, and to the right of, the umbilicus. Vermicular action of the intestine was seen from the right iliac region up to this lump. On palpation the lump could be easily felt; it was about two inches in diameter and of an ovoid shape and could be grasped between the thumb and fingers without causing pain. In the left iliac region some small indurated masses were felt resembling enlarged glands. Per rectum the finger passed in easily. At a point about three inches from the anus a sharp, sickle-like band was felt, apparently attached to the anterior wall of the pelvis and impinging on the rectum, and though not interfering with its calibre it would probably do so if the bowel was loaded. Examination of the chest discovered nothing abnormal. The pulse and temperature were normal. An enema was administered and brought away a quantity of small, scybalous masses. Examination of the abdomen after this failed to discover the small indurated masses in the left iliac region that had been mistaken for glands. The patient was given small quantities of milk which were retained. The most probable diagnosis appeared to be tuberculous peritonitis with partial occlusion of the transverse colon.

On July 17th, under ether, an incision about two inches long was made in the left linea semilunaris from the level of the umbilicus downwards. No evidence of tubercle was discovered. The band in the pelvis appeared to be a fold of peritoneum running along the whole of the anterior surface of the pelvis and projecting backwards about one inch. The lump in the epigastric region was felt to involve the pylorus. A second incision was made running upwards from the umbilicus in the middle line about two inches in length. The lump was then lifted out of the abdomen. It was found to consist of an enlargement of the cardiac end of the stomach close to the pylorus. The transverse colon was closely adherent, which caused a loop and would interfere with the free passage of its contents. The lump appeared to be connected with the walls of the stomach; it was ovoid in shape, about two inches in diameter, and tense and elastic. As the nature of it was uncertain it was decided to explore it. After separating the colon clamps were applied on either side and a longitudinal incision was made over it on its anterior aspect. About three drachms of clear serous fluid immediately escaped and the finger entered a cyst which had no communication with the stomach or intestine. The cyst wall was found to be attached to the muscular wall of the stomach. It was situated between this and the mucous membrane which it had pushed downwards. It was very intimately attached posteriorly, above, and in front. How much it had occluded the pylorus it was impossible to say as the fluid had escaped before the nature of the enlargement was discovered. An endeavour was made to dissect off the wall but it was so adherent that it was impossible to avoid penetrating the walls of the stomach and it was necessary to excise this portion. The ends were united with silk sutures and the abdominal wounds were closed. The patient suffered from considerable shock, after which he improved for a day or two, but died early on the 21st from exhaustion.

The specimen was sent to the Clinical Research Association and it reports as follows: "From the naked-eye appearance and microscopic structure of this cyst wall we can form no definite opinion as to its origin. It is composed of closely felted fibrous tissue which is smooth on one surface but entirely devoid of any epithelial covering. Externally there is loose cellular tissue and interlacing bundles of unstriped muscle. From the youth of the patient it is probable that the cyst is of congenital origin."

Necropsy.—Post-mortem examination showed some recent peritonitis. The anastomosis was quite secure. The crescentic band felt on the anterior wall of the pelvis consisted of a peritoneal fold projecting backwards from the posterior surface of the bladder and ending in a horn running up on each side wall of the pelvis just posterior to the position of the ureters. It stood out one and a quarter inches at the centre, gradually diminishing as it approached the sides. There was a second less marked peritoneal fold along the upper surface of the bladder.

Remarks by MR. STRETTON.—I can find no record of either of these conditions. Of the cyst I can offer no further explanation than that given by the Clinical Research Association. A congenital cyst in this situation must be exceedingly rare, if, indeed, it has ever before been found. The fold of peritoneum was no doubt an unusual development of the sacro-genital fold so well depicted in Professor D. J. Cunningham's "Text-book of Anatomy" (Figs. 822 and 823). Although always present. I have never before been able to feel it per rectum and so far have not heard of it being felt. In this opinion I am strengthened by a letter from Dr. D. Waterston of the University of Edinburgh who, in answer to a question from my house surgeon, Mr. W. A Wilson-Smith, says: "I have often wondered if it could not be felt per rectum but yours is the first instance to my knowledge." Both the conditions, therefore, appear to be worth reporting and it is a curious fact that they should have been found in the same abdomen.

DONATIONS AND BEQUESTS.—The late Mrs. H. Finnie has bequeathed £2000 to the Clevedon (Somerset) Convalescent Home and her executors have allotted the sum of £1000 to the Royal Sea Bathing Hospital, Margate, for the endowment of the "Hannah Finnie memorial bed."

Reviews and Notices of Books.

The Scientific Temper in Religion, and Other Addresses. By the Rev. P. N. WAGGETT, M.A., of the Society of St John the Evangelist. London: Longmans, Green, and Co. 1905. Pp. xii.-286. Price 4s 6*d*. net.

THE charming series of addresses delivered at various times in the form of sermons by the Rev. P. N. Waggett and now published as a book of essays under the general title of the "Scientific Temper in Religion" should be read by all thoughtful and philosophically minded men, and will especially appeal to members of the medical profession. The essays form no *apologia* to the Christian for his religion; they contain no polemical criticism of the tenets of science, and offer no presentation of the supposed antagonism between science and religion; they constitute rather a thoughtful and suggestive plea for mutual understanding, respect, and assistance on the part of these two great schools of thought and action.

In the introductory chapter Father Waggett points out that in what he terms "the upper regions of educated life" there is at the present time a pause in the controversy, making a good opportunity for mutual adjustment of differences. He terms this pause happily a "truce by estrangement" and he suggests that the cause of the cessation of hostilities is threefold. Firstly we have the readjustment of thought on the part of orthodoxy, whereby many religious statements are differently expressed and explained; secondly, we have the vigorous condition of natural science, its broader field of work, and the greater caution incidental to the increased broadness of view; and thirdly, the fact that the Church has been fully occupied with its own problems, notably in regard to the results of critical research and the Ritschlian theology. This last circumstance is well put by Father Waggett in the following sentence: "Men are much too hard at work in adjusting our new ideas of what religion is with the old words which already enshrine them to be keenly interested about dangers supposed to arise from friction between the Bible record and the discoveries of natural science." The result of this preoccupation of science and religion each with its own problems has been that each has advanced on its own lines ignoring the other in a spirit of despair of reaching agreement or coincidence. What is needed is a better mutual understanding, or again to quote from the volume under notice: "If in science we need and welcome a spirit and a method of patience, on the side of religion we need and ought to show a more truly scientific temper." Father Waggett points out that science and religion do not progress along coincident or even parallel lines but rather in converging directions; it is therefore not to be expected that they should entirely agree or even be able to express their tenets without discrepancies, but since both are advancing each should regard the work of the other with reverence, patience, tolerance, and moderation.

The second address is that which gives its title to the book, and in it the scientific temper in religion is defined, not as an attempt either to conciliate the statements of religion and science or to establish religion as a department of natural history, but as a desire to adopt the wide outlook, the adventurous spirit, and the positive temper of the highest scientific workers. Father Waggett shows the breadth of his views, and illustrates his contentions admirably, in the analysis he gives of the methods of science and in the application of these methods to the problems of religious experience. He refers to the adventurous spirit of science in speculative and theoretical fields and to the solid advance which the experimental testing of theory and hypothesis has led to; in illustration he refers to the great conceptions of natural selection and of the Mendelian theory of heredity, both of which have led to the discovery of new facts. He next refers to the adventure of science in actual discovery, the search with an open mind for new facts; and thirdly, to the excellent discipline of science, in which even in learning the simplest and most fundamental facts the actual personal verification of each fact observed by the student is of vital importance. The third essay follows naturally upon the second and is entitled "The Distribution of Problems." Here are classified and outlined various classes of modern difficulties. Four classes of such difficulties are distinguished: first, the contentions of materialism; secondly, there is the attack on the spiritual nature of man; thirdly, the attack on natural religion or theism—i.e., the general belief in God; and fourthly, the objections directed against Christian dogma or Bible religion. Father Waggett maintains that the doctrine of evolution does not in any sense come into conflict or antagonism with theism, and further states that the supposed antagonism between the theory of natural selection and the idea of God has been in no small measure due to the narrow conception of the latter idea in men's minds. In the next essay, on the Effect of Evolutionary Doctrine, Father Waggett quotes Professor Huxley in support of his contention that theism as such does not come into direct collision at all with the doctrine of evolution stated generally. He goes on to prove that theology is really assisted in its deeper studies by the conception of evolution—to use his words, "By the thought that what we see is not a perfect thing which shows its destined end but a growing thing whose nature is to be guessed by the indications of its purpose and not by the present and evident successes of its labour."

The fifth chapter is devoted to Agnosticism and Determinism, and here Father Waggett deals with two doubts which may arise in many minds—firstly, the suspicion that science alone is real knowledge and that other things which pass under that name are mere fancies, which he regards as agnosticism; and, secondly, that in the realm of science there is an inexorable binding by law, a denial of the idea of freedom which may be referred to as determinism. Father Waggett, with great ability, contends that freedom is not denied by the universality of law, that, indeed, freedom grows when law becomes clear and definite, and only in this way. In the sixth chapter the relation between Natural Selection and Theism is further developed. Father Waggett, while for the purposes of argument allowing the widest latitude to the theory of natural selection, points out that it does not account either for "the origin of life or for the origin of its character and behaviour." Further, he maintains that it does not account for variation and that therefore it does not come into conflict with that reverence for supreme creative power which forms one of the supports of religious conviction. The same idea is developed in the next chapter, under the heading of the Bible and Evolution, and after maintaining that the teaching of Genesis should be compared not with modern biology but with other ancient cosmogonies, Father Waggett claims that the Bible foreshadows some of the most striking and surest elements of modern thought, that it excludes the two extremes of dualism and scepticism, and that it affords a statement of truth in a form credible throughout the ages.

The eighth chapter is devoted to an analysis of the effect of biological doctrines on certain views of human nature. The conclusions of anthropological, physiological, psychological, and embryological studies are critically considered, while the idea of greater freedom in the realm where law is most evolved suggested in a previous essay is further developed. The last two chapters—on Experiment, Dogma, and the Aids which Science gives to the Religious Mind—are practically an application of the previously developed ideas to the use of religion and within the space of a review they cannot be outlined, especially as the author's matter does not lend itself to condensation. We have enjoyed the perusal of Father Waggett's book and can commend it to those of our readers who desire a thoughtful exposition of modern scientific ideas as applied to the problems of religious thought.

Atmokausis und Zestokausis: die Behandlung mit hochgespanntem Wasserdampf in der Gynäkologie. (*Atmokausis and Zestokausis: the Therapeutic Use of Superheated Steam in Gynæcology.*) By Dr. LUDWIG PINCUS. Second revised edition. With 33 figures and tables. Wiesbaden: J. F. Bergmann. 1906. Pp. 371. Price 6 marks.

THE application of steam to the interior of the uterus as a means of arresting hæmorrhage, although practised by but few persons in this country, is yet in Germany, at any rate, a well-recognised therapeutic measure. This is largely owing to the work and zeal of Dr. Pincus of Danzig, who has done more than anyone else to popularise this mode of treatment. In the second edition of his book the whole subject is very fully dealt with and after reading the evidence afforded by it, it will be impossible for anyone to deny that in certain well-defined conditions atmokausis and zestokausis are perfectly legitimate and useful methods of treatment.

The first part of the work is taken up with an account of the gradual development of the apparatus employed and of the experimental investigations which have been carried out as to the effects produced by the application of superheated steam to the interior of the uterus. The second part deals with the manner in which the application of the steam should be made to the uterus and with the indications for, and the contra-indications to, its use. In his summary of the history of the method Dr. Pincus points out that the use of boiling water in the treatment of fistulæ and sinuses was well known to Rust in the year 1813, but that K. H. Dzondi of Halle was the first to devise a satisfactory boiler for the ready production of steam for this and similar purposes. The disinfectant and hæmostatic properties of this agent were well known to the surgeons of that date, but its systematic employment as a hæmostatic was not really begun until the year 1886, when it was placed upon a definite footing in surgery by Snegirew of Moscow. The rest of this chapter deals in a most interesting manner with the way in which the various difficulties and dangers were overcome by the energy and determination of the author of this work, often, indeed, in the face of much opposition and scepticism on the part of the opponents of this method of treatment.

In order that good results may be obtained with atmokausis the rules laid down for its use by the author cannot be followed too carefully. Sufficient dilatation of the cervical canal must be produced by the use of dilators, or better by the use of a laminaria tent. Before the introduction of the steam into the uterus the cavity and the mucous membrane must be cleansed carefully from all blood and mucus, preferably with a 1 per cent. solution of peroxide of hydrogen. In all cases great care must be taken to determine the exact length of the uterus and of the cervical canal, and, further, that the uterine appendages and cellular tissues are in a perfectly healthy condition. In the majority of cases Dr. Pincus considers anæsthesia unnecessary, laying stress on the fact that if the patient complains of pain during the operation the introduction of the steam should at once be stopped. This mode of treatment can be practised on out-patients and on its first introduction this was considered to be one of its most important advantages, but it is on the whole safer to treat the patients on the same lines as if they had had the uterus curetted, and to keep them in bed as a precautionary measure for the same length of time.

In cases where there is any doubt as to the condition of the uterine appendages, or where these are painful on examination, the patient should be subjected to a course of suitable treatment, and steaming the uterus should only be carried out with the utmost care. One of the chief dangers of the use of so powerful an agent as superheated steam in the interior of the uterus is the fear of causing obliteration of the cervical canal, with a resulting collection of the menstrual blood in the interior of the uterus. This must be carefully guarded against, first of all by observing the rules never to introduce the catheter with the steam turned on, and secondly, never to withdraw it so far as to leave the tissues of the cervix unprotected by the special sheath of non-conducting material intended to shield them from the action of the steam. Great care must be taken also to see that neither the inlet nor the outlet tubes become blocked by blood clot. The best results are obtained by using steam at a temperature of from 110° to 115° C. for as short a time as possible—viz., from five up to 40 seconds. If the steaming is repeated this should not be done until from three to four weeks have elapsed or until after the occurrence of the next menstrual period.

The indications for the use of steam may be divided into absolute and relative. Included amongst the former are such conditions as certain forms of pre-climacteric hæmorrhage; all cases of hæmophilia with hæmorrhage from the uterus; certain forms of hæmorrhage in cases of fibro-myomata of the uterus; certain forms of endometritis hæmorrhagica and endometritis hyperplastica in young women and atonic hæmorrhages, especially after abortions or in the later stages of the puerperium; and for the sterilisation of women under certain conditions. As relative indications Dr. Pincus enumerates cases of subinvolution and cases such as membranous dysmenorrhœa in which it may be used as an accessory to the curette. Atmokausis is to be preferred to the curette when the latter instrument has already been employed without success, and especially in patients suffering from excessive anæmia in whom it is important to avoid any further loss of blood. Zestokausis, which is in reality merely a form of actual cautery, is indicated when a cauterisation of some localised portion of the endometrium is necessary, and in the treatment of some cases of so-called endometritis dysmenorrhœica. Atmokausis is undoubtedly a most valuable means of arresting hæmorrhage in certain well-defined cases. When used intelligently and with proper precautions it gives good results in such cases, and it often succeeds where curettage alone fails. Whether it produces a more permanent effect than the somewhat old-fashioned plan of applying pure acids, such as carbolic or nitric acids, to the uterus, after using the curette, is still doubtful; such applications often fail, however, in producing the desired effect, and Dr. Pincus and others have certainly proved that atmokausis when properly carried out is one of the most efficacious methods, if not the most efficacious, of arresting hæmorrhage from the uterus.

Recent Advances in Physiology and Bio-Chemistry. Edited by LEONARD HILL, M.B. Lond., F.R.S. Contributors: Leonard Hill, M.B. Lond., Benjamin Moore, M.A., D.Sc.; M. S. Pembrey, M.A., M.D. Oxon.; J. J. R. Macleod, M.B. Aberd.; and A. P. Beddard, M.A., M.D. Cantab. F.R.S.; London: Edward Arnold. 1906. Price 18*s.* net.

OUR German *confrères* have accustomed us to *résumés*, Centralblatts, and recently to "Ergebnisse" on various topics. This volume is a welcome departure in a similar direction by five English physiologists who have essayed with success to give a critical *résumé* of certain subjects that have specially attracted the attention of physiologists and of chemists in recent years. Even the word "bio chemistry," though it does not denote a new departure, foreshadows a new method of regarding the relations of chemistry and physiology. Dr. Moore, indeed, in his thoughtful essay on living matter goes further than either chemist or physicist and speaks of "biotic energy." The real problem before us is that of the chemical reactions and exchanges that are taking place in the cells—reactions that are really reactions in solution. Recent investigations have shown the enormous part taken by intracellular enzymes acting as energy transformers, and the chapter on the action of enzymes is well worthy of perusal. The intracellular enzymes—and they are many—are shown to be adapted, controlled, and coördinated by the cell. By a gentle transition we arrive at the "kinases," a section of the book that is of very great interest. The whole subject of secretion is fully dealt with. Indeed, what is often spoken of as secretion, absorption, and excretion are but different phases of the same process distinguished from one another not by things intrinsically different in their nature or in the mechanism by which these processes are carried out in the body, but rather by their object or physiological function. Moreover, respiration is essentially identical in its nature with these three processes and Dr. Moore treats the subject from this wide and comprehensive point of view.

Dr. Hill gives a capital account of the effects on life of lessening or increasing the barometric pressure, a subject which he has made specially his own. He also is responsible for the chapter on water in relation to metabolism and the regulation of body temperature, and for a chapter on metabolism of fat. Dr. Macleod deals with metabolism of the carbohydrates, a subject which naturally leads to the cognate question of diabetes, whether experimental, pancreatic, or produced by the administration of phloridzin or adrenalin. Proteid metabolism as such is not specifically dealt with but the questions connected with uric acid and the purin bodies absorb about 50 pages. By the same author we have another 40 pages on hæmolysins and allied bodies, a review of the work of the past few years on this and cognate subjects. Dr. Pembrey gives an account of respiratory exchange on well-known lines and to him falls also the subject of internal secretion. Perhaps this latter chapter might have been extended with advantage. Dr. Beddard deals with rather a heterogeneous group of subjects—namely, the production of lymph, absorption from the small intestine, the formation of urea, and the secretion of urine. As to lymph formation the author agrees that experiments have shown that the importance of osmosis and diffusion is relatively greater, and that of filtration relatively less, than has been thought to be the case. He gives a *résumé* of his views on p. 615.

This work will prove most valuable to all students of medicine reading for the higher examinations. Moreover, to the clinician it affords a *catena* of the views of the chief authorities on such subjects as diabetes, uric acid metabolism, hæmolysis and immunity, caisson sickness, and the therapeutic uses of oxygen, and, indeed, all the newer problems which have such special interest for the thoughtful clinician and practising physician.

Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India. (New Series.) No. 24. *On a Parasite found in the White Corpuscles of the Blood of Palm Squirrels.* By Captain W. S. PATTON, M.B. Edin., I.M.S. Issued under the authority of the Government of India by the Sanitary Commissioner with the Government of India, Simla. Calcutta: Office of the Superintendent of Government Printing, India. 1906. Pp. 14. Price, annas 12, or 1*s.* 2*d.*

SEVERAL hæmogregarinidæ have been discovered recently in the blood of mammals, and in view of the great importance which attaches to such forms the description of another example is of interest, especially as the parasite found by Captain Patton invades a special cell, the large mononuclear leucocyte. The mammal which harbours this parasite is the common, striped, palm squirrel of Kathiawar and Gujarat (Funambulus pennantii). Parasites belonging to the genus hæmogregarina have the following characters: they are elongated, fusiform bodies with the appearance of vermicules, and are seen lying coiled up in the cells or free in the plasma. They do not produce pigment and have no sexual form of development. In cold-blooded animals they are confined entirely to the red cells. Captain Patton discovered this parasite in May, 1905. On examining a drop of blood from an infected squirrel the parasite is seen as a clear elongated worm-like body measuring 10μ in length, lying in the substance of the large mononuclear leucocytes. The majority exhibit slow vermicular movements, altering their position in the cells. They may be seen lying close alongside the nucleus or at right angles to it. The nucleus becomes compressed, and in some instances almost encircles the parasite, while many of the nuclei are split into two separate parts, with the parasite lying between. The invaded leucocytes show extremely slight movements. Each body is oval with one end rounder than the other. The protoplasm contains a large refractile nucleus placed about the centre and some dark dots are seen moving in the protoplasm. The narrow end shows a distinct bend upwards simulating a tail. In fresh blood films containing a large number of parasites some of these bodies are seen escaping from the cells. After watching one, which appears particularly active, the more rounded end will be seen to cause the cellular envelope to bulge. It ruptures and the parasite is extruded. No space is left behind to show where the parasite was lying. Besides the encysted forms many are seen lying free in the plasma. They have the same appearance as those in the cells. The parasite stains readily with Romanowsky's stain and Leishman's modification. No distinct capsule can be made out by staining in the usual way, but by prolonged staining with Romanowsky's stain and also with Giemsa's a faint pink outline is seen around the parasite. Each stained body is oval in shape with one extremity larger and rounder than the other. It measures 10μ in length and 5μ across the broadest part. The protoplasm stains light-blue, somewhat darker at the two ends. The nucleus is a comparatively large irregularly quadrilateral mass, which lies about the centre. It occupies the whole of this part of the parasite, encroaching on the sides. It stains deeply but not uniformly, and contains from three to eight vacuoles. The protoplasm of all the invaded leucocytes stains feebly as compared with the normal cell.

In infected squirrels the large mononuclears form the bulk of the white cells; the mononuclear leucocytosis is found to vary in proportion to the degree of infection. The fact that a mammalian protozoon, which has the property of invading a special leucocyte, causes a change in the structure and an increase in the numbers of these in the peripheral blood may have some significance in relation to the origin of leucocythæmias. The parasites were always found to be present in the spleen. Special attention was directed to the liver in estimating the distribution of the parasite in the body. 14 squirrels were shot and smears were made from their livers. In all the parasite was found both free and in the mononuclear leucocytes, but no developmental forms were present. The parasite has been found in the body of the squirrel louse, which has been identified by Professor Neumann and Dr. Newstead as an undescribed species of hæmatopinus and is found in large numbers among the long hairs of the squirrel. Captain Patton draws the following conclusions from his researches. That the description of this parasite agrees in every detail with that of a hæmogregarine. That the parasite is highly specialised in that it selects the large mononuclear leucocyte for its host. Though closely related to leucocytozoön canis (James) it differs in not having a cytocyst and in possessing a tail. He proposes to name it provisionally leucocytozoön funambuli. As in the case of hæmogregarina gerbilli (Christophers) no developmental forms were found in the organs and the infection remains unaltered for long periods.

LIBRARY TABLE.

The Edinburgh Stereoscopic Atlas of Anatomy. Edited by DAVID WATERSTON, M.A., M.D. Edin., F.R.C.S. Edin., F.R.S. Edin., Lecturer and Senior Demonstrator in the Department of Anatomy, University of Edinburgh. Section 5. Edinburgh: T. C. and E. C. Jack. 1906. Price £1 5s. net. each section.—This being the fifth is the final section of the Atlas and Dr. Waterston is to be congratulated on the completion of his task. The last instalment is equal in interest to any of its predecessors. It is devoted to illustrations of the anatomy of the head and neck and the central nervous system, and to cranio-cerebral topography. The anatomy of the brain was in part depicted in the first part of the Atlas, but in the present section we find an additional series of ten illustrations which are excellent. We gather that these are views of specimens prepared by Dr. E. B. Jamieson who is also responsible for the brief descriptions which accompany them. We think that Dr. Waterston has been fortunate in obtaining Dr. Jamieson's coöperation, for the views in question are of great practical utility and give an excellent idea of some of the long tracts of the brain. The anatomy of the head and neck is fully illustrated, the nasal cavities, pharynx, and larynx being included. Ten views illustrate cranio-cerebral topography. These comprise illustrations of the child's brain and of that of the adult. By a method of composite photography the relations of the scalp, bones, and brain are shown in superposition. The value of these photographs is in a way limited, since everything is mapped out according to the method of Professor Chiene, a method which is not so well known as those methods which are associated with the names of Reid, Hare, Godlee or Anderson and Makins. In a note appended to the section Dr. Waterston dedicates the Atlas, with permission, to Principal Sir William Turner, K.C.B., whose researches and teaching have done so much to advance the science of anatomy both in this country and abroad.

Cheltenham. Burrow's Royal Series of Official Albums. No. 7. Written by J. H. GARRETT, M.D. Durh., Medical Officer of Health of Cheltenham. With 120 coloured and other illustrations. Published under the auspices of the Corporation and the Chamber of Commerce, Cheltenham, by Edward J. Burrow. Fifth edition. 1906. Pp. 163. Price 1s.—This official guide to Cheltenham was published under the auspices of both the Corporation and the Chamber of Commerce on the occasion of the opening of the new spa. The old fashion of drinking the Cheltenham waters, which was set by Royalty in the person of George III., subsided chiefly owing to the ease of foreign travel, but the use of the waters is now being revived. The wells are chiefly owned by the corporation, which body collects the waters and offers them in convenient forms, at several different places in the town, for the use of those who may desire them or who have been ordered to take them by a physician. The waters are mildly aperient, alterative, diuretic, and antacid and are of two kinds—the magnesia-saline and the alkaline-saline waters. The magnesia-saline is sold in a concentrated form, so that a moderate draught may have an aperient effect. Some excellent baths have been built by the corporation for use in conjunction with the mineral waters and it is stated in the album that any form of medicated or special bath that the physician chooses to order can be prepared and administered by trained attendants. The brine bath is a Cheltenham specialty. The fittings and decorations of the baths and the furnishing of the dressing-rooms appear to be of the first order. The Cheltenham spa should be deservedly popular, for the town compares favourably with other large towns in its general sanitary condition, and its climate possesses the two very essential features of a dry atmosphere and an abundance of bright sunshine. This album is a useful guide, the letterpress being interesting and the illustrations good. Its cost is only 1s.
